Organic Electron Donors

John A. Murphy

WestCHEM, Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, UK

1 INTRODUCTION

Organic molecules can behave as electron donors to form radical cations¹ and, subsequently, radicals under many conditions. They can do so spontaneously through encountering (i) a reagent or (ii) a partner substrate that has sufficient oxidizing power, or they can be induced to donate an electron photochemically, electrochemically, or under exposure to radiation conditions (including mass spectrometry). This article focuses on neutral organic molecules that are prone to oxidation by electron transfer, either intrinsically or under the conditions of the reaction, whether in intermolecular or intramolecular manner. The coverage will certainly be selective rather than comprehensive. This article forms part of the Volume on Chemical Synthesis and so deals with reactions that may be used in synthetic studies, rather than a stricter definition of reactions that have been used in the synthesis of a natural or unnatural product. The article does not set out to cover reactions in biology or materials chemistry; those topics are for other authors. There is undoubtedly some overlap with other articles in this work, and at such instances the reader is referred to those; however, it is also useful to see something of the broad scope of organic molecules that can act as electron donors in one article.

2 SPONTANEOUS OR THERMAL ELECTRON TRANSFER TO PARTNER SUBSTRATES

This section describes reactions that occur at various temperatures including room temperature and

below, but they do not require activation by photochemical, electrochemical, or other methods. Molecules with nonbonding electrons are prime candidates for such reactions. Recently, Ishibashi *et al.*² have shown that tripropylamine reacts with diphenyldisulfide at 140 °C to give reactions with all the hallmarks of radical chemistry (Scheme 1), and it is proposed that the radicals are generated by single electron transfer (SET) to the disulfide by the amine. The thiyl radicals then add to alkenes and alkynes—thus enyne **1** affords the cyclopentenenes **3** (8%) and **4** (35%), and the cyclohexene **7** (33%); a cyclopropylcarbinyl radical rearrangement (**2** → **5** → **6**) is proposed to account for the formation of the six-membered ring. This builds on earlier examples using 1,4-dimethylpiperazine as the electron donor.³

Heteroatom-substituted alkenes have featured prominently in electron transfer reactions. The ground-state SET chemistry of enamines, enols, and their derivatives with various oxidizing reagents is considered later in this article. In general, they do not undergo electron transfer with organic acceptors in the ground state; for example, with good organic electron acceptors such as arenediazonium salts, enamines undergo a simple nucleophile–electrophile reaction.^{4,5} (Scheme 2). However, when additional heteroatoms are present on the alkene, the nature of the reaction can change. The chemistry of electron-rich olefins has been reviewed.⁶ Tetrathia-alkenes are widely known and their electron transfer chemistry is dominated by the special case of tetrathiafulvalene and its analogs.

Scheme 1

2.1 Tetrathiafulvalenes

Wudl synthesized the parent tetrathiafulvalene (TTF) **8**, and characterized its radical-cation salts

Scheme 2

Scheme 3

9 in 1970;⁷ substituted analogs of **8** had been prepared earlier.^{8,9} The credentials of TTF in electron transfer, particularly in materials chemistry and supramolecular chemistry, are reflected in the 30 000 citations for “TTF” currently on the ISI Web of KnowledgeSM.

TTF is easily oxidized in the presence of appropriate substrates, but relatively stable to air unless photoactivated, and this stability is reflected in its availability from commercial chemicals suppliers. The oxidation potentials for TTF have been determined as $E_1^0 = +0.32\text{ V}$; $E_2^0 = +0.71\text{ V}$ versus saturated calomel electrode (SCE) in MeCN,¹⁰ involving sequential oxidation to a radical cation **9** and to a dication **10**. In the dication **10**, the aromaticity can be fully expressed (Scheme 3).

TTF forms complexes with electron-poor organic molecules such as 7,7,8,8-tetracyanoquinodimethane (TCNQ),¹¹ but as these have been used primarily in materials chemistry and as they have become so extensive, they are beyond the scope of this article and the reader is referred to an excellent review.¹²

Scheme 4

Reaction of TTF with diazonium salts as organic oxidants was first mentioned in the Russian literature; these papers focused on the formation of the TTF radical cation **9** rather than on the fate of the arenediazonium entity^{13,14} and this was followed some years later by oxidation of TTF by hypervalent iodine compounds.^{15,16}

Murphy *et al.* reported that reaction of appropriately substituted arenediazonium salts **11** (Scheme 4) led to spontaneous evolution of nitrogen and formation of the aryl radical **12**.^{17,18} Cyclizations of aryl radicals afforded **13**, which trapped the TTF radical cation, **9**, derived from TTF, to afford **14**. For substrate **11a** (i.e.,

Scheme 5

Scheme 6

R = R' = H), this product, **14a**, was quite stable, while for **11b** and **11c** the final product was the corresponding alcohol **16** when moist acetone was used as solvent. The nonsubstitution at a primary carbon in **14a** and the ready substitution at the secondary and tertiary carbons revealed this substitution as an S_N1 reaction, and evidence emerged later (see below) that the Ar–O grouping is required to trigger the displacement of the TTF from **14b**.¹⁹ In the formation of **15**, TTF is displaced and so, in principle, the compound can behave as a catalyst,²⁰ but its turnover number was not high, and investigations unearthed a number of possible novel side-reactions of TTF sulfonium salts.²¹

In principle, sequential C–C and C–S bond formation reactions might occur via an intermediate aryl cation rather than an aryl radical, but several factors disprove this. The regiochemistry of ring formation in **13** (five-ring rather than six-ring) is consistent with the kinetic properties of radical cyclizations. Also, arenediazonium salts can be converted into aryl cations on heating but are usually stable at ambient temperatures in solution (no spontaneous loss of N_2 occurs from most diazonium salts); furthermore, if aryl cations were intermediates arising from the decomposition of arenediazonium salts in this reaction, then the role of the sulfide would be as a cation trap,

Scheme 7

Scheme 8

Scheme 9

and this role could be fulfilled by sulfides other than TTF. However, trials showed that dimethyl sulfide did not trigger such reactions and did not form similar sulfonium salts, and hence the reaction is caused by the easily oxidized TTF undergoing electron transfer to the easily reduced arenediazonium salts.²² Because the overall reaction sequence featured a radical C–C bond formation and a nonradical C–O bond formation occurring by S_N1 chemistry, it was called the “radical-polar crossover” reaction, and afforded a new type of termination for aryl radicals. This traverse from radical to nonradical pathways has now been seen in a range of different types of reaction, and the term “radical-polar crossover” describes more than this TTF reaction in the literature. The reaction was extended to formation of amides instead of alcohols,

when dry acetonitrile was the solvent. Here, the intermediate cationic intermediates **15** are trapped in a Ritter-type reaction and the resulting nitrilium salts afford acetamides **17** on hydration.¹⁷

The reaction worked well in the synthesis of dihydrobenzofurans and indolines, and this led to its being harnessed as the key step in the synthesis of (±)-aspidospermidine **24** (Scheme 5).^{23,24} The conversion of diazonium salt **18** to alcohol **19** follows the path laid out for the formation of **16**. Inherent in this synthesis is the control of relative stereochemistry. The initial indoline formation occurs with cis ring-junction stereochemistry as is well preceded in radical cyclization reactions, leading the interception of carbocation intermediate by water to take place on the less crowded exo or β-face to afford **19**. Following oxidation

Scheme 10

Scheme 11

to the ketone **20** and introduction of the ethylidene side-chain in **21**, the ketone was reduced to give an alcohol (α -stereochemistry) that was then displaced in an intramolecular Mitsunobu reaction to yield tertiary amide **22**. Further functionalization led to the formation of the final six-membered ring in **23**, and then hydrogenation and deprotection afforded ($\pm$)-aspidospermidine **24**.

As mentioned above, and as represented by structure **15**, the participation of the Ar–X heteroatom in displacing the TTF-derived sulfonium group was of key importance. A number of studies established that the absence of such a group prevented displacement of the sulfonium salt. Substrate **25** illustrates this point: reaction with TTF afforded the aryl radical **26** that displaced the cyclohexyl radical **28** in forming the methoxy dihydrobenzothiophene **27** (Scheme 6). The latter compound was converted into benzothiophene **29** under the conditions of the reaction, but the sulfonium salt **30** was not hydrolyzed, since in contrast to the analogous TTF salt **14**, no neighboring group was present to facilitate this. Diazonium salt **31** shows that the neighboring group does not need to be an aryl ether;

here, the silyl ether group effects the displacement within TTF salt **32**¹⁹ to afford **33**.

The conversion of arenediazonium salts to aryl radicals was accomplished efficiently at room temperature by an SET from TTF. Although TTF can lose a second electron in being oxidized to disalt **10**, this is relatively more difficult, and no evidence of aryl anion formation was seen with this system in reactions with diazonium salts. Comparison of the redox potentials is instructive: for TTF, $1 E^0_1 = +0.32$ V; $E^0_2 = +0.71$ V versus SCE in MeCN,¹⁰ while for an arenediazonium salt, the first electron transfer occurs at about -0.2 V versus SCE in DMF²⁵ or in MeCN.¹⁰ Even though the process appears energetically uphill, the formation of an aryl radical is accompanied by irreversible loss of dinitrogen, driving the reaction to completion. On the other hand, although the *standard* potential for reduction of an aryl radical to an aryl anion was later determined by Andrieux and Pinson²⁶ at 0.05 V versus SCE, a second electron was not transferred. (In practice, we find that the donor must have a potential circa -1 V to afford aryl anions by a second electron transfer.)

Scheme 12

The importance of aromatic stabilization energy in the oxidation of TTF had been apparent since its first synthesis. Under the same conditions in which TTF **8** had been instantaneously reactive, the dibenzoTTF **34** compound was not able to liberate N₂ from arenediazonium salts. Here, the aromatic stabilization associated with oxidation to

radical cation **35** or the dication **36** would be less than for TTF. The newly created aromatic five-membered rings in **35** and **36** were already partly aromatic due to the benzo fusion in **34**. In the search for stronger donors, Cava, Garito, and coworkers²⁷ had shown that the difficult-to-prepare sulfide **37** was a stronger donor than TTF, due to

Scheme 13

the aromatic stabilization energy associated with its oxidation, but characterization of this molecule was a challenge because of its sensitivity to oxidation. This compound shows only an irreversible oxidation in acetonitrile quoted at $E_p = -0.14$ V (if this is relative to standard hydrogen electrode (SHE), this would equate to -0.38 V vs SCE) (Scheme 7).

2.2 Polyaza-Substituted Ethenes

Dithiadiazafulvalenes (DADTFs) had been well investigated,^{28–30} and their oxidation had been studied. It was clear that replacing some of the sulfur atoms within TTF by nitrogen atoms afforded much more powerful donors. For example Bakker *et al.* showed that the tetraester **38** (Scheme 8) is a better reducing agent than TTF, despite the presence of the electron-withdrawing ester groups.³¹ This is due in

large measure to the stabilizing effect of the nitrogen atoms on the cationic system following oxidation, compared to sulfur.

The dibenzodiazadithiafulvalenes, being stronger donors than TTF **8**, were also able to reduce arene-diazonium salts. Murphy *et al.* treated diazonium salt **11a** with DADTF **39**.^{32,33} The contrast between sulfur and nitrogen atoms became immediately apparent, as the same products were not afforded from this reaction as from the TTF reactions. Instead, fragmentation of the intermediate **40** occurs, because of the great reactivity of the nitrogen lone-pair, leading to the ketiminium salt **41**, thereby deviating from the radical-polar pathway of TTF and affording amide product **42**.

TTF may be the most cited of the tetra-heterosubstituted alkenes, but its discovery was predated by another important molecule, namely, tetrakisdimethylaminoethene (TDAE), **44**, discovered in the industry laboratories of DuPont in

Scheme 14

1950.^{34,35} This molecule has been examined by cyclic voltammetry and provides reversible oxidation at more negative potentials than the molecules discussed so far above. The oxidation potentials for this molecule had been determined as $E^0 = -0.78$ and -0.61 V versus SCE in MeCN.³⁶ This compound has found widespread use as an electron donor since its discovery. Its oxidation potential shows as two separate peaks in acetonitrile, but as a single peak in DMF. Crystal structures of its dication salts have been determined, and show rotation of about 70° between the N–C–N planes.³⁷

Defluorination occurred when triazoline **43** was treated with TDAE **44** to afford triazole **46**.^{38,39}

(Scheme 9). The byproduct was the difluoride salt **45**. Chambers *et al.* converted fluoroalkenes, for example, **47** to fluorodienes **48** with TDAE.⁴⁰ These reactions were proposed to occur by electron transfer to the electron-deficient alkene **47** and expulsion of fluoride ion followed by another electron transfer and another loss of fluoride ion to afford **48**. More recently, formation of *o*-quinomethanes by dehalogenation of 1,2-bishalomethyl arenes by TDAE has been explored.^{41,42}

It is clear that this donor is sufficiently strong to donate two electrons to highly electron-poor halides where the resulting carbanions are well stabilized. This molecule has principally been used to transfer

Scheme 15

two electrons to electron-deficient substrates such as CF_3I and $\text{ArC}(\text{Br})\text{F}_2$ to form the corresponding trifluoromethyl anions or difluorobenzyl anions⁴³ that react with aldehydes^{43,44} (Scheme 10) and with acid chlorides.⁴⁵ These substrates appear to receive two electrons, presumably sequentially rather than simultaneously, and evidence of radical intermediates has been reported with substrate **49**. Here, the addition of the electron donor TDAE **44** is performed slowly and reaction of the benzyl radical **52** with dihydrofuran **50** affords intermediate radical **53**, followed by bromine atom-transfer from the substrate to give good yields of bromide **51**.

TDAE has been used to couple α -bromoketones, for example, **55** $\rightarrow$ **56** (Scheme 10). It is unclear whether one electron is transferred to form the radical followed by a coupling of radicals to form the product or whether two electrons are transferred to one molecule of bromoketone to form the enolate anion that then displaces bromide from another molecule in an $\text{S}_{\text{N}}2$ reaction.⁴⁶

TDAE has also been used to reduce a range of arenediazonium salts, including **57–63** (Scheme 11), via aryl radicals to cyclized products.⁴⁷ For **57–61**, radical cyclizations are followed by loss of the PhSO_n radical to afford the alkene products **64** and **65**. The reaction of substrate **62** likely involves aryl radical cyclization onto the vinyl bromide to afford an intermediate cyclohexyl radical **67** that can expel the neighboring bromine to form an indolenine **68**, which on work-up tautomerizes to the indole **66**.

Reaction of diazonium salt **63** affords three products **71**, **73** and **74**. The intermediate aryl radical **69** either undergoes cyclisation to afford ultimately the isolated tetracycle **74** (60%), or abstracts a hydrogen atom to afford radical **70**. This radical principally afford indoles **71** (5%) and **73** (33%). It is possible that indole **73** arises from the indolenine **72**.

TDAE has even played a role in metal-catalyzed reactions. Here, it has been used in conjunction with chromium/nickel species for allylation of aldehydes and ketones⁴⁸ and for vinylation of aldehydes⁴⁹ using allyl and vinyl bromides, respectively, as well as with palladium^{50–52} in the homocoupling of aryl halides.

Combining the two factors above that produce strong donor characteristics, that is, (i) gain in aromatic stabilization energy on oxidation and (ii) the presence of nitrogen atoms to stabilize

the radical-cation and dication products of oxidation, leads to stronger donors than TDAE. Bourson first described⁵³ the deprotonation of a 1,3-diphenylbenzimidazolium salt **75** to form the tetraazaalkene **76** in 1971 (Scheme 12), followed by Hünig's synthesis of **77** and a study of the redox properties in 1972.^{54,55} Benzimidazole-derived compounds were also the focus of two papers from Thummel in 1995.^{56,57} In 1996, Taton and Chen reported⁵⁸ the preparation of a stable tetraazafulvalene **78** derived from imidazole and also reported on the stability of this and related compounds. The bis-tetramethylene-bridged compound **79**, on warming to room temperature, changed from the vibrant yellow crystals to a white solid, which turned out to be the dissociated bis-carbene **80**, attesting to the reactivity of the bridged compound. The bis-trimethylene bridged compound **78** was more stable and in the absence of air and moisture showed no signs of decomposition, allowing an X-ray crystal structure to be obtained on **78**. All of these compounds are extremely reactive to oxygen. In 1997, Ames *et al.* made a thorough overview of the oxidation potentials of these molecules as seen in cyclic voltammetry.⁵⁹ From all these studies,

Scheme 16

it was clear that the oxidation potentials of the imidazole donors were more negative than those of the benzimidazole derivatives. This is in line with greater aromatic stabilization energy arising from the oxidation of the imidazolylenes.

Murphy *et al.* applied donor **81** to the reduction of aryl iodides and alkyl iodides.⁶⁰ This afforded aryl radicals, as seen in the cyclization of **87** to indoline **88** (Scheme 13). Although the oxidation potential was significantly less negative than the aryl iodides (−1.8 V), efficient reaction took place (assisted by the irreversible loss of iodide), while although the oxidation potential was significantly negative of the reduction potential of the aryl radicals (+0.05 V),²⁶ no reduction to aryl anions took place!

The involvement of alkyl radicals in the reactions of alkyl iodides was seen not only in cyclizations, for example, **89** → **90** but also in the neophyl rearrangements (see **Radical Rearrangements: Ester-Substituted Radicals and Hydrogen Atom Migrations and Intramolecular Homolytic Substitutions in Synthesis**) of radical **92** derived from iodide **91**, leading to isolation of the products **93** and **96**. If alkyl anion had formed in this reaction (or if a two-electron reaction were present, to be more precise) elimination to α -methylstyrene **98** would have been a likely product, but none was seen.

The cyclization of aryl iodide substrates like **87** with donor **81** was in contrast to the outcome with donor **78**; this more powerful donor leads to

Scheme 17

the formation of aryl anions by transfer of two electrons.⁶¹

While reduction of aryl radicals to aryl anions is relatively easy, as determined by Andrieux and Pinson,²⁶ reduction of alkyl radicals to alkyl anions is much more difficult. Hence, it was of great interest when treatment of alkyl iodides and bromides, for example, **99**, afforded homologated aldehydes (**100** in this case) on reaction in DMF with donor **78** (Scheme 14).⁶² However, the origin of the aldehyde carbon was not the DMF but rather the donor, and it appears that this reaction results from trapping of alkyl radicals **101** by the radical cation of the donor **86** to form key intermediates **102**, followed by a fragmentation process, leading to the formation of the aldehyde (**100**). Related experiments supported the intermediacy of iminium salts **103** and enamines **104**; thus, reaction of substrates **107** led, via trapping of alkyl radicals, to liberation of the alcohols ROH and R'OH in good yields, with the proposed mechanism as shown in Scheme 15. Here, enediamine **108** and

dienediamine **110** expel alkoxide leaving groups as they form salts **109** and **111**. More recently, similar chemistry has been reported for the donors **81** and **113**.⁶³ (Donor **113** is easily prepared from 4-dimethylaminopyridine (DMAP) by deprotonation of the intermediate disalt **112**.)

Sulfonamides, *gem*-disulfones,^{64,65} acyloin derivatives,⁶⁶ and Weinreb amides⁶⁷ all undergo cleavage with these strong donors, presumably via sequential SET steps.

The range of recently prepared neutral ground-state organic molecules being studied for their electron transfer properties includes the intriguing structures **114–116** (Scheme 16). Compounds **114** and **115** have been studied by Vaid.^{68,69} In both cases, oxidation can result in extensive aromaticity arising in a number of linked rings. Cyclic voltammetry of compound **114**⁶⁸ shows that only two oxidative peaks appear (−1.33 and −1.14 V vs Fc/Fc⁺, corresponding to −0.88 and −0.69 V vs SCE), one relating to the transfer of four electrons and the other to the transfer of

In MeCN, 70% **136**, 5% **137**
In MeOH, 30% **136**, 60% **137**

Scheme 18

two electrons. Redox chemistry of **115**⁶⁹ occurs at -1.48 V versus Fc/Fc^+ , corresponding to -1.03 V versus SCE; investigations into the nature of ground-state **115** were ambiguous about whether the molecule exists as a diradical or as a closed-shell species.

Himmel^{70,71} prepared **116** and tested its redox properties by cyclic voltammetry; this molecule showed a two-electron wave at $E_{1/2}(\text{MeCN}) = -0.32$ V, but computational studies suggested that in nonpolar solvents **116** could be a stronger donor even than **78**.

Scheme 19

3 PHOTOELECTRON TRANSFER

One of the most intriguing ways of generating radicals in synthetic chemistry is by photoactivation (see **Synthetic Radical Photochemistry**). The ability of simple aliphatic amines and their derivatives to transfer an available electron into a hole created by photoexcitation of a partner reagent has produced some beautiful chemistry over the past few decades. Addition of triethylamine to benzene **117**, in the presence of methanol as a proton source, affording dihydrobenzene **118** was accomplished⁷² as early as 1971 (Scheme 17), but addition to alkenes and, in particular, to α,β -unsaturated carbonyl systems is more prevalent in the literature.⁷³ In these cases, electron transfer from the amine to a photoexcited acceptor affords the amine radical cation **119**. Deprotonation, for example, by the radical anion of the electron acceptor then gives radical **120**. Efficient and highly stereoselective examples of this reaction type are seen in Hoffmann's work of irradiation of substituted benzophenone sensitizers at 350 nm.⁷⁴ Here, the use of such sensitizers that feature electron-donating groups in the aryl rings, for example, **123**, **126** was found to be

important.⁷⁵ An example is the formation of **124**, using *N*-methylpyrrolidine **122**. In this case, the chiral auxiliary is present as an acetal on substrate **121**, and later removal is easy. For some amines, such as triethylamine, thiocarbonyl compounds, such as **127**, assist the efficiency of the addition as seen in the formation of **128**.⁷⁶

Amines that are α -substituted by metals or by carboxylate groups have special properties. On electron transfer, the amine radical cation **129**, undergoes decarboxylation to afford radical **130** (Scheme 18). In contrast to conversion of **119** to **120**, where deprotonation can occur at any C–H adjacent to the nitrogen, the carboxylate substitution here places the radical selectively at one specific carbon and, with speedy decarboxylation, this can simplify the subsequent radical chemistry.^{77–82} Synthetic applications of the carboxy-substituted cases have been substantially developed by Griesbeck^{79–82} and are elaborated in the article **Synthetic Radical Photochemistry**.

On the metals side, Mariano has engaged in a long-term study⁸³ of photoinduced electron transfer of α -trimethylsilylmethylamines, such as **135**. The reactions of the amine radical cation **131** that is

Scheme 20

formed by electron transfer to an acceptor, can be determined by the nature of the solvent and by ionic additives such as lithium salts. Thus, the aminyl radical cation **131** is more likely to be deprotonated by an acceptor radical anion to form radical **132**, if that radical anion is basic. This basicity can be decreased by addition of lithium salts and by adding a hydrogen-bonding solvent that breaks up the radical cation (derived from donor)–radical anion (derived from acceptor) contact ion-pair. Slowing down the deprotonation gives a chance for the alternative reaction, desilylation, to occur, and with a silophilic solvent, for example, MeOH desilylation of **131** is encouraged, thereby forming radical **133**. As with the decarboxylation, this desilylation leads to regioselective radical formation, and the speedy desilylation adds to the efficiency of the reaction. This change of solvent and salt additives can lead to the preferential formation of different products, as seen above in the reactions of silylamine **135** with cyclohexenone **134** affording predominantly the silylated product **136** in acetonitrile and the desilylated compound **137** in methanol.^{84,85}

More recently, Mariano has focused on phthalimides as the electron acceptors for silylamines and for other silyl compounds. An example that reflects the relative efficiencies of the desilylation versus nondesilylation pathways is shown in Scheme 19.⁸⁶ When acetonitrile is the solvent, the excited state singlet phthalimide in **138** can abstract a hydrogen atom via a six-centered transition state; the resulting radical pair **139** then leads to a mixture of products **141** (via **140**) and **142** (28%, 18%, respectively), with **143** (21%) also produced. (A similar outcome arises for the nonsilylated analog **144**.⁸⁷) However, irradiation of **138** in 35% H₂O in MeCN results in 96% of the benzopyrrolizidinone **143**. This results from direct electron transfer from the C–Si σ -bond to the excited state phthalimide and affords a radical-cation–radical-anion pair. Desilylation leads to specific formation of the radical pair **146** that then couples efficiently to form **143**.⁸⁶

The singlet excited states of phthalimides can receive an electron from different groups including an α -silylamine or an α -silylamide.⁸⁶ However, desilylation of the radical cation of the amides to afford a radical occurs much more rapidly than for the amine, and this means that there is decreased time for back-transfer of the electron. In turn, this results in more selective and quantum-efficient processes. Thus amine **147** affords **148** (28%) and

149 (21%), while sulfonamide **150** affords **151** in 92% yield (Scheme 20).

An attractive application of this knowledge is featured in a study of acceptor phthalimides, in molecules that have more than one potential donor group.^{88,89} In the cases of **152**–**155**, protonation of the amines prevents them from taking part in the reaction and allows the ether oxygen lone pairs to be involved in the electron transfer (Scheme 21). It appears that equilibrium is set up between the possible oxygen radical cations, but that the oxygen radical cation adjacent to silicon undergoes rapid desilylation to afford the α -alkoxyalkyl radical at that site; this radical then couples with the phthalimide ketyl radical. The notable points about

Scheme 21

Scheme 22

these reactions are that the ring size is controlled by the site of the silicon, and that the yields of the products **156–159** appear to vary little for the different ring sizes formed. This strategy has also been used to make macrocyclic amides.⁹⁰

Demuth's work on photoelectron transfer produced some intriguing biomimetic cyclizations of isoprenoid precursors.⁹¹ For example, the pentalkene **160** underwent photoexcitation to afford an alkene radical cation, which then triggered a consecutive radical cyclization to afford the steroidal product **161** as the major product, with complete control of the stereochemistry (Scheme 22). This selectivity is thought to be due to the preorganization of the isoprenoid chain in the transition state for

cyclization, which was conducted at -25°C . The absolute stereochemistry in this example is controlled by the menthol acetal auxiliary that can be easily removed following the reaction to afford **162**.

The aim of inducing stereochemical control in complex radical processes in a catalytic sense has been addressed both by the singly occupied molecular orbital (SOMO) catalysis of MacMillan (see **Synthetic Radical Photochemistry**) and also by Bach's electron transfer (PET)-activated cyclization of the pyrrolidino-pyridone **163** to afford tetracycle **164**. A special sensitizer was used for this reaction with the aim of organizing the conformation of the precursor–acceptor complex through π stacking and H bonding (shown in red) in **165** (Scheme 23). The detailed mechanism of the reaction has not been reported.

Scheme 23

4 REAGENT-INDUCED ACTIVATION

Ground-state molecules can also be electron donors to reagents of growing popularity; some of the reagents that trigger this process will now be discussed in brief.

4.1 Ceric Ammonium Nitrate (Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry)

The chemistry of this reagent has recently been reviewed.⁹³ This strong oxidant converts alkenes, and particularly electron-rich alkenes to radical cations. Thus, the oxidation of the silylenol ether

Scheme 24

166 (Scheme 24) leads to radical cyclization and oxidative rearomatization to **167**.⁹⁴ Oxidation of the cyclopropyl sulfide **168** to its radical cation leads to cleavage of the three-membered ring;⁹⁵ the resulting distal radical cation can be oxidized and trapped by the intramolecular alcohol and by water present in the solvent methanol as nucleophiles to afford **169**. Oxidation of the ether **170** to its radical cation can trigger loss of the ArCH_2 group; interception by the vinyl acetate would then lead to tetrahydropyranone **171**. The substitution on the aryl ring is crucial, and in this case, *p*-methoxyphenyl is used.⁹⁶ Oxidation of β -dicarbonyl compounds as **172** leads to the preferential formation of tetralones **173** or dihydrofurans **174**, depending on the solvent.⁹⁷

Very recently, ceric ammonium nitrate (CAN) has been employed by MacMillan in the oxidation

of enamines as a key part of his organocatalysis with SOMO activation. In general, CAN is the strongest of the oxidizing reagents used for enamine oxidation in his work. More selective oxidants that are required for certain reaction types are referred to later in the review.

In these reactions, aldehyde **176** combines with amine **175** to form the enamine **177** *in situ* (Scheme 25). The stereoselectivity of the ensuing process relies on the fact that the enamine adopts the *E* configuration lying away from the bulky *t*-butyl group. With the top face shielded by the benzyl group, the radical (most easily represented as **178'**) attacks the alkene of the allylsilane to afford radical **185**.^{98,99} (Only this SOMO-catalyzed reaction leading to the allylated aldehyde **188** is discussed here in mechanistic detail in this article,

Scheme 25

but analogous pathways lead to **180**¹⁰⁰ and **184**.¹⁰¹) Oxidation of this radical affords the stabilized cation **186**, which undergoes nucleophile-assisted loss of the silyl group giving alkene **187**. Hydrolysis *in situ* then liberates the substituted aldehyde and the catalyst can trigger further enamine formation as it continues the catalytic cycle. It is noteworthy that the enamine undergoes oxidation by CAN far faster than the amine **175**.

With styrenes as radical acceptors, MacMillan illustrated that aldehydes could be converted to benzylic nitrates. An example is shown in Scheme 26 where the aldehyde-derived enamine **189** is oxidized to its radical cation, which

undergoes radical addition to styrene to afford adduct radical **190**. In turn, this radical is oxidized by CAN to a benzylic cation **191** that is trapped by nitrate ion derived from CAN¹⁰² to afford product **192**.

With the same type of reactivity and catalyst, Nicolaou reported an α -arylation of aldehydes by arenes bearing electron-donating groups. In this case also, the oxidant was CAN.^{103,104} Thus, aldehyde **193** was converted to its enamine and oxidized to a radical cation; addition to the aryl ring, oxidation, and deprotonation restored the aromaticity and enamine hydrolysis provided product **194**. This

Scheme 26

approach was used in a short synthesis of demethyl calamenene **195**.

4.2 Iron Reagents

In a very similar approach, MacMillan reported that $\text{Fe}(\text{phen})_3 \cdot (\text{PF}_6)_3$ provided the best levels of yield

and ee, and used the arylation of aldehyde **196** as the key step (72% yield and 93% ee) in a synthesis of (–)-tashiromine **197**.¹⁰⁵ In the arylation of the radical cation intermediates, the question arises as to whether this is a radical-type cyclization or a cationic Friedel–Crafts type cyclization, and this has been analyzed.¹⁰⁶

The tris-phenanthroline iron(III) complexes were also the oxidants of choice for reaction of

Scheme 27

Scheme 28

Scheme 29

3-arylpropionaldehydes with styrenes, conjugate dienes, and allylsilanes (Scheme 27). A thiophene example, **198**, is shown that was converted with considerable selectivity into **199**, but other electron-rich arenes can also undergo this reaction (anisoles, indoles, benzofurans). The formation of the cyclopentane **201** from allylsilane **200** shows that the range of terminating nucleophiles can be extended further, and that the good selectivities are not confined to the preparation of six-membered rings.¹⁰⁷

Enamines are not the only compounds oxidized by iron complexes. Historically, phenol oxidative coupling has been triggered by iron(III) compounds. This will not be dealt with at length here and the reader is referred to an excellent recent review.¹⁰⁸ An example of such an oxidative coupling is shown

with the conversion of substrate **202** to alkaloid kresigine **203** (Scheme 28).¹⁰⁹ The exact nature of the intermediates of many of these reactions has not been determined, but the fact that iron(III) is a one-electron oxidant and that electron paramagnetic resonance (EPR) signals have sometimes been reported suggests that radical cation intermediates play a crucial role.

Alternative reagents are of course capable of performing these reactions and, among these, thallium(III) salts¹¹⁰ and vanadium(V) predominate. An impressive example, using VOF_3 is shown in the conversion of **204** to **205** in approaches to the vancomycin antibiotics (Scheme 29).¹¹¹

Amines can also be oxidized by iron salts, and this was important in the synthesis of vinblastine **211** accomplished by Kutney.¹¹² Thus, treatment

Scheme 30

of catharanthine **206** with ferric chloride formed the radical cation **207** that underwent fragmentation; further oxidation likely led to **209**, which was intercepted by vindoline, acting as a nucleophile, to afford **210** (Scheme 30). In the original Kutney paper, this intermediate was reduced and later transformed further to vinblastine **211**, but Boger has recently found a one-pot route with ferric oxalate, $[\text{Fe}_2(\text{ox})_3]$, sodium borohydride, and air to afford the alcohol **211** directly and quite efficiently (41% of **211** together with 20% of its hydroxy-epimer).¹¹³ This should provide easier access to analogs of the important anti-cancer agent, vinblastine.

An alternative iron-based reagent is the ferrocenium hexafluorophosphate **214**. This oxidizes the ester enolate **213**, derived from malonate **212**, to the radical **215**. Cyclization, and further oxidation, affords cation **217**, which then undergoes desilylation to yield **218** (Scheme 31). Jahn has used this methodology for the synthesis of a range of cyclic products.^{114,115}

4.3 Copper Reagents

While CAN is used for the most robust of the SOMO-catalyzed processes, milder oxidants provide enamine radical cations for other processes. MacMillan has seen enantioselective polyene cyclization based on radical cations (cf. the work of Demuth⁹¹ discussed above) using $\text{Cu}(\text{OTf})_2$ as the oxidant and sodium trifluoroacetate as the mild base. The efficacy of the approach is seen in the preparation of **221** from trienal **219** using catalyst **220** (Scheme 32). Even more adventurous examples are also successful with a 63% yield of a heptacyclic analog of **221** that includes formation of six new C–C bonds in the cyclization, with control of 11 contiguous stereocentres, of which five are all-carbon quaternary stereocenters.¹¹⁶

A further and important example of SOMO catalysis was reported in the interception of enamine radical cations derived from oxidation of enamines formed from aldehydes **222** with amine **223**. The

Scheme 31

Scheme 32

simple chloride sources NaCl or LiCl performed the interceptions with excellent stereocontrol. The produced α -chloroaldehydes **224** were converted, with full maintenance of enantiomeric excess, into the terminal epoxides **225**. As with all of these transformations, this conversion is compatible with a wide range of functional groups in R (Scheme 32).¹¹⁷

4.4 Manganese Reagents

The addition of acetic acid to alkenes mediated by manganese triacetate was first described in 1968.^{118,119} This reaction expanded in synthetic utility when β -dicarbonyl compounds were studied. A great deal of information has been gleaned through careful mechanistic and synthetic studies, and the reader is referred to reviews.^{120,121} The α -alkyl substituted β -ketoesters **226** and the α -unsubstituted β -ketoesters **230** react in surprisingly different ways (Scheme 33). The substituted esters lead to slow formation of a Mn(III) enolate **227**, followed by rapid homolysis of the Mn–O

bond to form a free radical **228** that adds rapidly to alkenes to form radical **229**. The intermediate radical **228** appears unbound since it behaves identically to a radical generated by other methods. On the other hand, the α -unsubstituted β -ketoesters **230** form a manganese(III)-enolate **231** rapidly, and this is followed by a slow addition to an alkene to form a radical product **232**. In this case, it is not thought that a free radical forms prior to the addition to the alkene, although radical **232** results from the addition.

Regardless of source, once the radical resulting from addition to an alkene has formed, its fate depends on its substitution pattern. Tertiary radicals can be oxidized to carbocations by $\text{Mn}(\text{OAc})_3$, while secondary and primary radicals cannot be. Primary radicals can abstract hydrogen atoms, but they are frequently oxidized by the additive $\text{Cu}(\text{OAc})_2$ to give reactive Cu(III) intermediates that can undergo reductive elimination to form Cu(I) byproducts and alkenes. Secondary radicals can also follow this pathway or can be oxidized to carbocations by Cu(II).^{122,123} Representative cyclizations of substrates **233** and **234** featuring Cu(II)-based terminations are shown.

Scheme 33

4.5 Aminium Cation-Radical Salts

It is not only metal compounds that can receive electrons from organic substrates. Among organic compounds, the triarylaminium radical cations feature widely.¹²⁴ The cyclopropane **235** has been oxidatively rearranged to the alkene **236** (Scheme 34) by Little, by means of mediated electron transfer.¹²⁴

The tris(4-bromophenyl)aminium cation is generated *in situ* electrochemically; this then

mediates the oxidation of the cyclopropane to form the radical cation **238**. This undergoes cationic migration to afford the seven-membered ring intermediate **239** and the resulting radical is thought to oxidize the triarylamine to continue the cycle and afford the product **236** (85%). This product was then transformed into Daucene **237**.¹²⁵ In another excellent and earlier example, a very efficient ring expansion from **240** to diquinane **241** was observed by Adam, Heidenfelder, and Sahin.¹²⁶ In this case,

Scheme 34

catalytic quantities of the aminium radical cation were used without electrochemical activation.

One of the principal reaction types that are triggered by aminium cationic radicals is the

oxidation of conjugated dienes to their radical cations. Schmitt and von Segern have explored¹²⁷ the mechanistic details of the cycloadditions of ketenes to cyclopentadienes, as well as other

Scheme 35

cycloadditions. An example is the cycloaddition of **242** and **243**. The thermal reaction leads to the formation of cyclobutanone **245**, while the aminium-catalyzed process affords the “Diels–Alder” products **244**.

4.6 Hypervalent Iodine Reagents

Hypervalent iodine compounds¹²⁸ can oxidize a number of functional groups to their radical cations. In an elegant synthesis that employs such compounds in three separate steps, Kita *et al.* announced the synthesis of (±)-Makaluvamine F, whose trifluoroacetate salt is shown as **252**,¹²⁸ by coupling components **249** and **251**, in 86% yield (Scheme 35). Radical cations arising from oxidations of the substrates with hypervalent iodine reagents were the proposed intermediates for each

of the transformations of **246** → **247**, **247** → **248**, and **250** → **251**.

5 ELECTROCHEMICAL INDUCTION

High-yielding oxidative electrochemical transformations involve the reaction of the cation radical of an enol ether derivative with a furan in substrates **253** en route to Alliacol A **255**,^{129,130} and **256**—a precursor to the arteannuin ring skeleton in **257**^{131,132} (Scheme 36). Trauner has also elegantly demonstrated the power of anodic oxidation using reticulated vitreous carbon (RVC) electrode twice in the syntheses of (–)-Heptemerone B and (–)-Gaunacastepene E **260**.¹³³ For deeper insights into electrochemical oxidations, the reader is referred to article **Electrochemically Initiated Radical Reactions** of this encyclopedia.

Scheme 36

6 CONCLUSION

In summary, electron-donating properties of organic molecules exhibit a wide range of reactions for use in synthesis. The diversity of the chemistry and the rapid developments that are seen currently testify to the wide usefulness of this route for the generation of radicals and radical cations in preparative chemistry. This article showcases the recent use of radical cations in organocatalysis as one of the fastest moving areas that has applications to diverse reactions. We can expect that this will continue to develop rapidly in the near future. At the same time, the flexibility of synthesis of highly reducing organic structures suggests that the current impressive frontiers of neutral organic compounds as super-electron-donors may soon again be breached, and that these molecules may soon challenge the most powerful reducing metals in achieving difficult reductions. The development of elegant electrochemistry is also an area of great promise, particularly at a time when “reagentless” chemistry has environmental attractions, and recent demonstrations of the power of photoelectron transfer in synthesis, as represented in this article, also herald an impressive future.

1 INTRODUCTION

Samarium diiodide (SmI_2) was first prepared at the turn of the twentieth century,¹ but it was not used as a reagent in organic synthesis until it was introduced to organic chemists by Kagan in 1977.² It has since attained an importance reserved for few reagents and is now a standard reductant in most synthetic laboratories. The unique place held by SmI_2 in the arsenal of synthetic chemists is a result of its versatility in mediating numerous important organic reactions that proceed through free-radical intermediates. These selective reactions include functional group reductions, reductive couplings, and cascade reactions. The use of SmI_2 often allows alternative routes to multifunctional targets to be considered. Although numerous SmI_2 -mediated reactions have been developed, its scope in synthesis is far from exhausted and new applications for this reagent continue to be discovered. This article provides a “snapshot” of the organic chemistry mediated by SmI_2 . The importance of additives and the mechanism of reactions is also discussed.

Samarium, like other lanthanides, has a shell core configuration of $[\text{Xe}] 4f^n 6s^2$. The loss of the three outermost electrons, namely, the $5d^1$, $6s^2$ electrons, results in enhanced thermodynamic

stability in which a closed-shell Xe-like electronic configuration is adopted resulting in a thermodynamically stable +3 oxidation state across the lanthanide series. The +2 oxidation state is most relevant for samarium (f^6 , near half-filled), europium (f_7 , half-filled), thulium (f^{13} , nearly filled), and ytterbium (f^{14} , filled). To attain the more stable +3 oxidation state, SmI_2 readily gives up its final outer-shell electron, in a thermodynamically driven process, making it a very powerful and synthetically useful single-electron-transfer reagent.

The reducing power (reduction potential) of SmI_2 has been established through the use of linear sweep and cyclic voltammetry and was found to be approximately -1.41 V, determined for a solution of SmI_2 in tetrahydrofuran (THF).^{3,4} Although the preparation of SmI_2 in a variety of different solvents is known, THF is the most common solvent associated with its use because of the high solubility of the reagent. It is possible to alter the reduction potential of SmI_2 through the use of various additives, most commonly neutral or Lewis basic oxygen functionalities. The most common example of this is the use of hexamethylphosphoramide (HMPA) as an additive, for which it was determined that, upon incorporation of 4 equiv, the reduction potential of SmI_2 in THF is increased to approximately -1.79 V, thereby significantly increasing its potency as an

electron-transfer reagent.^{4–6} Similar effects are also observed in the presence of alcohols and even water, for which it has been reported that, upon the addition of 500 equiv, the reduction potential can be increased as far as -1.9 V.⁷

The solvent milieu and the additives employed in reactions of SmI_2 have a significant impact on the coordination sphere and the reactivity of the reagent. Samarium, like other lanthanides, is oxophilic so a great deal of the coordination chemistry of SmI_2 is dominated by oxygen-containing solvents and ligands. In a THF solution, SmI_2 exists in a hepta-coordinate geometry in which five THF molecules are equatorially bound to the central Sm(II) ion through their oxygen lone pairs, with iodine ligands bound axially.⁸ The coordination number and geometry of SmI_2 is variable depending on the nature of the ligands involved. For example, in the $[\text{SmI}_2(\text{HMPA})_4]$ complex, the more sterically demanding HMPA ligands are positioned equatorially around the Sm(II) ion resulting in an octahedral (hexacoordinate) geometry.^{9,10} Other common additives such as glycols and glymes produce coordination numbers as high as eight ($[\text{SmI}_2\{\text{O}(\text{CH}_2\text{CH}_2\text{OMe})_2\}_2]$) and nine ($[\text{Sm}\{\text{O}(\text{CH}_2\text{CH}_2\text{OH})_2\}_3\text{I}_2]$).^{11,12} The high coordination number coupled with the oxophilic nature of SmI_2 is beneficial for stereoselective reactions. The coordination of Sm(II) and Sm(III) to oxygen donors on substrate, solvent, or cosolvent provides a means for achieving a high level of selectivity in reactions.

2 THE REAGENT AND THE EFFECT OF ADDITIVES

Although SmI_2 is commercially available as a 0.1 M solution in THF from a range of suppliers, it is straightforward to prepare. The two most convenient procedures involve addition of either 1,2-diiodoethane or iodine to a slight excess of samarium metal in THF.^{13,14} After stirring the mixture for several hours, the characteristic dark blue solution of SmI_2 is formed in concentrations up to 0.1 M (Scheme 1).

The solution is stable for extended periods as long as it is stored in an inert atmosphere. Several other approaches for the rapid synthesis of SmI_2 have been developed. Concellón has shown that sonication of a solution of samarium metal

Scheme 1 Convenient preparation of SmI_2 .

with iodoform, 1,2-diiodoethane, diiodomethane, or iodine in THF provides SmI_2 within 5 minutes.¹⁵ Similar results can be achieved by microwave heating.¹⁶

When necessary, SmI_2 can be prepared in solvents other than THF. Kagan has reported formation of the reagent in tetrahydropyran (THP),¹⁷ and Ruder reported the use of acetonitrile.¹⁸ Interestingly, Tani has shown that SmI_2 can be prepared in a solution in benzene and HMPA.¹⁹ More recently, Flowers showed that high-intensity ultrasound could be used to facilitate the preparation of SmI_2 in low concentrations (0.02–0.05 M) in acetonitrile, dimethoxyethane (DME), 2-propanol, 2-methyl-2-propanol, and 2-heptanol.²⁰ Attempts to prepare SmI_2 in ethereal solutions other than THF, including diethyl ether, *tert*-butylmethyl ether, and dioxane have been reported to be unsuccessful.¹⁷ One of the unique features of SmI_2 is the use of cosolvents or additives to control reactions. For example, cosolvents and additives can be used to control the rate of reduction or chemo- and stereoselectivity of reactions. Additives commonly utilized to alter reactions of SmI_2 can be classified into three major classes:

1. Lewis bases—HMPA and other electron donor ligands, chelating ethers, and so on;
2. Proton donors—predominantly alcohols, glycols, and water;
3. Transition-metal salts— NiI_2 , FeCl_3 , and so on.

Lewis bases containing basic oxygen or nitrogen are important promoters of reactions initiated by SmI_2 . Among these additives, HMPA has played an important role in the development of the chemistry of SmI_2 . The unique potential of the SmI_2 –HMPA combination was first recognized by Inanaga who discovered that the use of this additive significantly increased the rate of reduction of alkyl and aryl halides.²¹ Since Inanaga's initial studies, HMPA has been employed in a wide range of functional group conversions and bond-forming reactions, which

are discussed in subsequent sections of this article. Several research groups have studied reactions initiated by SmI_2 –HMPA and have uncovered a complex role for the additive. Coordination of HMPA to SmI_2 not only produces a more powerful reductant but also displaces iodide ligands to the outer sphere of samarium, creating open coordination sites for substrates while concomitantly producing a sterically encumbered reductant.^{3,4,6,22,23} HMPA also plays a critical mechanistic role in post-electron-transfer events in SmI_2 -mediated reactions. Addition of HMPA retards the rate of bimolecular coupling of biaryl ketyl radicals through complexation of Sm(III) that bridges colligating radical anions.²⁴ Conversely, HMPA accelerates SmI_2 -initiated 5-*exo*-trig ketyl–olefin cyclizations through conversion of the intermediate Sm(III) -ketyl radical contact ion pair to a solvent-separated ion pair.²⁵ More recently, Flowers has shown that HMPA activates alkyl halide bonds, providing the basis for selectivity in samarium Barbier reactions.²⁶

While the behavior of HMPA is unique and there are many synthetic advantages to its addition to reactions involving SmI_2 , safety hazards make its use undesirable. Other Lewis basic cosolvents have been utilized successfully in reactions with SmI_2 ; these include 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone (DMPU),^{27–29} 1,1,3,3-tetramethylurea (TMU),³⁰ and nitrogen donor solvents.³¹ More recently, tripyrrolidinophosphoric acid triamide (TPPA) has been employed as an additive in SmI_2 -mediated reactions, and it is reported that the complex formed between SmI_2 and 4 equiv of TPPA possesses greater reactivity than the corresponding complex containing HMPA.³² In many of these reactions, a relatively large excess of additive is required. Although all of the aforementioned Lewis bases have found uses in specific reactions, none has yet been shown to provide the general utility of HMPA.

Many reactions of SmI_2 require the presence of a proton donor to quench the carbanion and alkoxide intermediates formed during the course of a reaction. The most common proton donors are water, alcohols, and glycols. Proton donors often have a considerable impact on the regiochemical and stereochemical outcome of SmI_2 -mediated reactions. For example, Keck has shown that the efficiency and stereoselectivity of the reduction of β -hydroxy ketones by SmI_2 in THF is dependent upon the proton donor employed and

its concentration.³³ In another important example, Procter showed that γ,δ -unsaturated ketones undergo two very different stereoselective cyclization reactions mediated by SmI_2 depending upon the alcohol cosolvent used in the reaction.³⁴

Several studies have shown that the basis for selectivity in many reactions is related to the affinity of the proton donor for SmI_2 .^{28,35,36} In particular, water was found to have a higher affinity for SmI_2 compared to alcohols and generated a more powerful reductant.⁷ The activation of SmI_2 by H_2O is best illustrated by Procter's recent findings that simple lactones can be reduced using SmI_2 – H_2O .^{37,38} These studies led to the proposal that glycols capable of chelating through multiple interactions should enhance rates of reduction by SmI_2 , and there are a number of examples where glycols have been used to accelerate SmI_2 -initiated reductions.^{39–42} Care should be taken when using chelating alcohols since it has been shown that low concentrations of glycols enhance the reactivity of SmI_2 whereas high concentrations lead to coordinative saturation of samarium resulting in a less reactive reductant.¹²

In some cases, proton donors can be used in concert with Lewis bases to provide unique methods for increasing the reactivity of SmI_2 . This is best exemplified by the work of Hilmersson, who has shown that the appropriate stoichiometry of water and amine with SmI_2 can be used to reduce a range of functional groups or carry out selective deprotections.^{43–46} This method not only provides an alternative to HMPA, but also has several advantages including fast reaction times and precipitation of inorganic by-products, making workup straightforward.

Inorganic salts are another important additive used to enhance the rate and selectivity of SmI_2 -mediated reactions. The use of inorganic additives can be traced to the seminal studies of Kagan during which he used catalytic amounts of ferric chloride to accelerate the coupling reactions of alkyl iodides and ketones.¹³ The most commonly utilized salts are based on Fe(III) or Ni(II) , and Kagan has shown that NiI_2 was superior to other transition-metal salts in many of these reactions.⁴⁷ As a result, NiI_2 has become the additive of choice in reactions requiring a transition-metal-based catalyst. NiI_2 has been used in a range of important reactions including the conjugate addition of alkyl iodides to α,β -unsaturated esters, amides, and lactones,^{48,49} the coupling of acid chlorides

and esters,⁵⁰ intramolecular cyclizations and Grob fragmentations,⁵¹ and the coupling of alkyl halides with nitriles.⁵²

3 THE MECHANISMS OF REACTIONS USING SAMARIUM DIIODIDE

Most bond-forming reactions using SmI₂ produce radicals and subsequently anions by the reduction of alkyl halides, or ketyl radical anions by the reduction of carbonyl groups.

3.1 Reduction of Organohalides

The reduction of aryl or alkyl halides by SmI₂ provides access to radicals that can undergo a range of follow-up reactions including hydrogen atom abstraction from solvent, dimerization, or reduction to an anion as shown in Scheme 2. The mechanism for reduction of alkyl and aryl halides to form

Scheme 2 Fate of radicals formed by reduction of organohalides with SmI₂.

an initial radical is recognized to proceed through dissociative electron transfer.

The presence of additives alters the reduction significantly. The addition of HMPA to reactions of SmI₂ and primary or secondary alkyl halides in THF leads to a radical **1** that is rapidly reduced to an organosamarium intermediate **2**. In the presence of a proton donor (alcohol, water, glycol, etc.), the organosamarium intermediate is protonated to form **3**. If an electrophilic carbonyl is present, it can capture the intermediate organosamarium to form a new C–C bond **4** (Scheme 3).⁵³

Reduction of tertiary alkyl halides by SmI₂–HMPA produces organosamarium species of limited stability.⁵⁴ The reduction of aryl and vinyl halides depends on the solvent milieu and the presence of additives. For example, vinyl and aryl halides are reduced to radicals by SmI₂ and subsequently abstract a hydrogen atom from THF. To circumvent this process, Tani utilized SmI₂–HMPA in benzene to prepare aryl organosamarium intermediates.⁵⁵

An understanding of the impact of solvent and substrate structure as well as the role of additives is crucial in the design of new reactions mediated by SmI₂. Additionally, a knowledge of reaction rates is indispensable for planning new processes. Curran's work on hexenyl radical clocks determined the rate of reduction of primary, secondary, and tertiary radicals by SmI₂–HMPA.⁵⁶ This data is important when any proposed radical reaction using SmI₂ is considered. For example, radical-based reactions must be faster than the rate of reduction of the radical, and, similarly, any proposed anionic process must take into account competition from fast radical reactions. The data provided from this work is shown in Scheme 4. It is important to note that the efficiency of radical reduction is dependent

Scheme 3 Effect of HMPA on the reduction of organohalides with SmI₂.

Scheme 4 Rates of reduction of alkyl radicals with SmI_2 -HMPA.

Scheme 5 Issues of regioselectivity in an attempted Barbier reaction.

upon the amount of HMPA present in the reaction medium.

Radical reduction is inefficient when HMPA is absent, and typically 4–5 equiv [based on (SmI_2)] is necessary in most alkyl halide and radical reductions. Rate data for the reduction of radicals to organosamarium intermediates allows an element of predictability but problems can arise when multifunctional substrates are involved. For example, in the attempted intramolecular Barbier reaction of alkyl iodide **5**, treatment with SmI_2 results in the formation of side product **7** in addition to the expected product cyclohexanol **6** (Scheme 5).

In this case, the β -keto amide motif in **5** is reduced at a rate competitive with alkyl iodide reduction, indicating that there are likely two mechanistic pathways through which the reaction proceeds: a thermodynamic pathway initiated by reduction of the R–I bond providing the cyclohexanol **6**, and a kinetic pathway involving chelation of SmI_2 to the β -keto amide and reduction of the ketone carbonyl group to give **7**.⁵⁷

3.2 Reduction of Carbonyls

The reduction of a carbonyl by SmI_2 is the first step in a number of bond-forming reactions and reductions of synthetic importance. These reactions include reduction to alcohols, pinacol coupling, and carbonyl–alkene couplings. In many of these reactions, the use of additives including HMPA and proton donors is critical for their success. The initial electron transfer from SmI_2 to a carbonyl results in an intermediate ketyl radical anion **8** that can form dimeric **9** or higher order ion pairs (Scheme 6).⁵⁸

The equilibrium in the initial reduction is dependent on the identity of substituents and the presence of additives. In dialkyl ketones and alkyl aldehydes, the equilibrium lies to the side of the starting substrate. The presence of aryl groups stabilizes the ketyl radical anion, and in benzophenone derivatives the equilibrium lies toward the ketyl radical intermediate and reductions are fast. Addition of HMPA

Scheme 6 Monomeric and dimeric ketyl radical anions.

or proton donors, or the presence of a neighboring functional group, also drives the equilibrium toward the ketyl intermediate. Although the reaction shown in Scheme 5 provides an example in which a neighboring functional group leads to an unproductive pathway, proximal functional groups can be useful for enhancing the rate of carbonyl reduction and enhancing the stereoselectivity of reductions. This is best exemplified by the work of Keck who showed that β -hydroxy ketones are stereoselectively reduced by SmI_2 using methanol as a proton donor source (Section 4.2).³³ While the identity of the proton donor source has an impact on the reaction outcome, the key feature of this reaction is the intermediacy of a chelated intermediate. Kinetic studies by Flowers have shown that the presence of a chelation pathway dramatically increases the rate of reduction of carbonyls by SmI_2 .⁵⁹

It is important to recognize that more distant Lewis basic functional groups can also coordinate to SmI_2 , altering reactivity and stereoselectivity. For example, eight- and nine-membered chelates have been invoked to rationalize the stereoselectivity observed in a number of reactions.^{60,61} This facet of SmI_2 -mediated chemistry should be kept in mind when employing the reagent in reactions involving highly functionalized substrates.

HMPA also has a marked impact on carbonyl reduction using SmI_2 . Elegant studies by Daasbjerg and Skrydstrup have shown that addition of 4–10 equiv of HMPA produces $[\text{Sm}(\text{THF})_2(\text{HMPA})_4]\text{I}_2$ and further addition beyond 10 equiv likely produces $[\text{Sm}(\text{HMPA})_6]\text{I}_2$.⁶ Additionally, coordination of HMPA to SmI_2 provides a more powerful reductant and carbonyl groups are reduced at a faster rate. Mechanistic work by Flowers has shown that the rate of reduction of dialkyl ketones increases by 1–2 orders of magnitude upon the addition of 4–10 equiv of HMPA.²² The results of these studies are consistent with coordination of ketyl radical anion to $\text{Sm}(\text{III})$ even in the presence of 10 equiv

of HMPA. While addition of HMPA increases the rate of reduction of dialkyl ketones by SmI_2 , aryl aldehydes and acetophenones provide “head to tail” coupling products. Fang proposed that, after initial reduction of aryl aldehyde, the $\text{Sm}(\text{HMPA})$ coordinated ketyl radical anion **10** is too sterically encumbered to dimerize through pinacol coupling.⁶² As a consequence, a second reduction occurs to produce dianion **11**, which reacts with substrate to provide **13** after workup. In this example, HMPA plays an important mechanistic role in post-electron-transfer events by altering the reactivity of the ketyl radical anion formed from the carbonyl (Scheme 7).

Recent mechanistic work has revealed several examples of the importance of HMPA after the initial electron transfer. Hoz has studied the mechanistic role of HMPA in reactions involving the ketyl radical formed from 4,4'-dichlorobenzophenone.²⁴ This study showed that increasing the amount of HMPA led to a decrease in the rate of coupling to give the pinacol product. $\text{Sm}(\text{III})$ is required for the bridging in **9**, which is a prelude to dimerization. Hoz proposed that increasing the amount of HMPA reduces the concentration of $\text{Sm}(\text{III})$ available for bridging through competitive coordination with the metal, thus decreasing the rate of coupling. HMPA has also been shown to play an important role in post-electron-transfer steps in carbonyl–alkene coupling reactions. This carbon–carbon bond-forming reaction provides an important route to cyclic alcohols, and the presence of HMPA is often important for obtaining high yields and diastereoselectivities in the transformation. A recent mechanistic study has shown that HMPA plays a further mechanistic role after the initial electron transfer (Scheme 8). Not only does coordination of HMPA to $\text{Sm}(\text{III})$ stabilize the intermediate ketyl **14**, but this coordination also inhibits cyclization. An additional molecule of HMPA liberates the contact ion pair to produce solvent-separated ion

Scheme 7 “Head to tail” coupling of benzaldehydes and acetophenones.

Scheme 8 Role of HMPA in post-electron-transfer steps.

pair **15**, thus relieving the steric constraints that inhibit cyclization.²⁵

Addition of proton donors including alcohols, glycols, and water to SmI_2 also have a profound impact on the rate and mechanism of carbonyl reduction. Kinetic studies by Flowers have shown that the rate of ketone reduction is directly related to the $\text{p}K_{\text{a}}$ of the alcohol proton source used in the reaction and that the proton source must be sufficiently acidic to protonate the ketyl radical anion intermediate produced after the initial electron transfer.³⁶ Hoz has studied the role of 2,2,2-trifluoroethanol as a proton donor in the reduction of benzophenones by SmI_2 .⁵⁸ This study

showed that protonation of dimer **9** (Scheme 6) is an order of magnitude faster than protonation of monomeric ketyl **8**. This allows one to control the follow-up reactions of ketyl radicals generated using SmI_2 (Scheme 9). For example, the use of trifluoroethanol leads to fast protonation of **8** or **9** and formation of intermediate radical **17** and pinacol **18**. If protonation of the ketyl is slow, reduction of **17** provides alcohol **19** through a traditional House mechanism (Scheme 9).

The ability of proton donors to coordinate to SmI_2 also has an important impact on carbonyl reduction. The presence of a coordinated alcohol during reduction of a carbonyl by SmI_2 places

Scheme 9 Importance of protonation on the fate of ketyl radical anions.

the proton in close proximity to the developing negative charge on the ketyl radical anion, facilitating rapid proton transfer. As a consequence, the reduction of less reactive carbonyl substrates is accelerated by high-affinity proton donors such as water. The enhanced reactivity is best exemplified by Procter's work using the $\text{SmI}_2\text{-H}_2\text{O}$ in the reduction of lactones and cyclic diesters, substrates that are highly resistant to carbonyl reduction by electron transfer.^{37,38,63,64} Under certain circumstances, glycols significantly accelerate the rate of carbonyl reduction by SmI_2 . The seminal work of Hilmerisson showed that coordinating alcohols enhance the rate of ketone reduction substantially and that the rate increase is proportional to the number of ethereal oxygens in the proton donor source.⁴² The mechanistic basis for this acceleration is also likely to be related to the proximity of the proton donor to the carbonyl being reduced. Interestingly, a large excess of glycol leads to a decrease in the rate of some reactions. For example, Flowers has shown that addition of glycol sufficient to fill the coordination sphere of SmI_2 decreases the rate of substrate reduction through the production of a sterically encumbered complex that is unable to coordinate to the ketone substrate.¹² Follow-up studies by Procter and Flowers have shown that high-affinity proton donors including water and glycols displace iodide ligands to the outer sphere of $\text{Sm}(\text{II})$ while leaving open coordination sites for carbonyl coordination.⁶⁵ As a consequence, these additives can be used to carry out

a range of bond-forming reactions and reductions usually reserved for $\text{SmI}_2\text{-HMPA}$.

4 FUNCTIONAL GROUP TRANSFORMATIONS MEDIATED BY SAMARIUM DIIODIDE

Reductants are one of the fundamental classes of reagent used to carry out functional group transformations and SmI_2 is one of the most versatile members of this class. The SmI_2 -mediated reduction of a number of functional groups, often in the presence of other groups, underpins the reagent's ability to mediate carbon–carbon bond-forming reactions, where reactive intermediates are formed, from functional groups, and trapped. The Lewis acidic nature of SmI_2 means that coordination to functional groups facilitates electron transfer. In addition, the $\text{Sm}(\text{III})$ salts that are produced as by-products can enhance the leaving ability of those groups to which it can complex, thereby facilitating their loss. As discussed in Section 2, additives and cosolvents can be used to fine-tune the reactivity of the reagent according to the functional group to be reduced.

4.1 Reduction of Alkyl Halides Using SmI_2

SmI_2 reduces alkyl halides with the following order of reactivity: iodides > bromides > chlorides. In the

Scheme 10 Alkyl halide reduction.

absence of activating additives, the SmI_2 -mediated reduction of primary alkyl iodides and bromides (but not chlorides) to the corresponding alkanes can be achieved under reflux in THF.¹³ Inanaga found that the more powerful reductant obtained by the addition of HMPA to SmI_2 allowed the reduction of alkyl halides to be carried out under milder conditions (Scheme 10).²¹ A detailed discussion of the mechanism of alkyl halide reduction can be found in Section 3.1.

The ability of SmI_2 to reduce alkyl halides is routinely exploited in a number of carbon–carbon bond-forming reactions. Radicals generated from the reduction of alkyl halides can be trapped by alkenes in cyclization reactions (see Section 7), while the alkylsamarium intermediates can be used in intermolecular and intramolecular Barbier and Grignard reactions (see Section 8). The reduction of α -halocarbonyl compounds generates $\text{Sm}(\text{III})$ enolates that undergo Reformatsky reactions (Section 9). The reduction of α -halocarbonyl compounds is discussed in Section 4.4.

In the presence of HMPA, SmI_2 is a useful reagent for the reduction of alkyl halides. Primary, secondary, and tertiary alkyl halides as well as alkenyl and aryl halides are reduced rapidly under these conditions, often in the presence of other functional groups (Scheme 10).^{21,56,66,67}

The reduction of alkyl halides with SmI_2 has been used to trigger β -elimination and the formation of alkenes.⁶⁸

4.2 Reduction of Ketones and Aldehydes Using SmI_2

SmI_2 reduces aldehydes and ketones to the corresponding alcohols. In some cases, SmI_2 can display useful reactivity, stereoselectivity, and chemoselectivity that conventional hydride reagents cannot achieve.

The reduction of aldehydes and ketones using SmI_2 (and other low-valent metallic reagents) generates a metal ketyl radical anion **20** that can form dimeric or polymeric ion pairs **21**.^{69,70} In the presence of a proton source, the O–M bond of the metal ketyl radical anion is protonated to form a carbinol radical **22**. Further reduction then forms a hydroxyalkyl carbanion **23**, and protonation gives an alcohol product (Scheme 11).^{69,70}

Further discussion of the mechanistic details of carbonyl reduction and the impact of additives can be found in Sections 2 and 3.2. Ketone reduction using SmI_2 can be highly diastereoselective. For example, in Corey's synthesis of the diterpenoid natural product atractyligenin,

Scheme 11 Reduction of aldehydes and ketones.

Scheme 12 Ketone reduction in natural-product synthesis.

SmI₂-mediated reduction of ketone **24** proceeded with complete diastereocontrol to give secondary alcohol **25** in 90% yield (Scheme 12).⁷¹

Keck has reported the diastereoselective reduction of β -hydroxy ketones with SmI₂ to give 1,3-*anti* diols.³³ For example, reduction of **26** with SmI₂ in THF with MeOH gave 1,3-*anti* diol **27** in 95% yield and 98% de. The reaction proceeds by initial coordination of Sm(II) to the free hydroxyl, followed by intramolecular electron transfer to the ketone carbonyl to form a ketyl radical anion. A second electron transfer gives alkyl-samarium **28**, in which the C–Sm bond adopts a pseudoequatorial position owing to the steric demand of samarium and its associated ligands, before being protonated by MeOH to give **27** (Scheme 13).³³

Keck showed that protection of the β -hydroxyl group in β -hydroxyketones as *t*-butyldimethylsilyl and benzyl ethers shuts off reduction, underlining the importance of pre-coordination of Sm(II) to the β -oxygen.³³ However, small ether-protecting groups are tolerated as they still allow coordination to Sm(II).⁷² Keck has also reported the diastereoselective reduction of β -amino ketones using SmI₂ in THF, with MeOH as the proton source.⁷³

In 2006, Xu and Lin reported a rare example of asymmetric reduction using SmI₂. For example, reduction of 2-acylarylcarboxylate **29** using SmI₂ and a catalytic amount of a chiral proton source gave chelated anion **30** that was protonated by enantiomerically pure oxazolidinone **32**. A stoichiometric achiral proton source 2,2,6,6-tetramethylpiperidine then regenerated the

Scheme 13 Directed reduction of β -hydroxyketones.

Scheme 14 Asymmetric ketone reduction.

chiral proton source. Lactone **31** was obtained in excellent yield and high enantiomeric excess (Scheme 14).⁷⁴

The SmI_2 -mediated reduction of ketones to give ketyl radical anions can result in the cleavage of a carbon–carbon bond α to the carbonyl group. This is a particularly efficient process when the carbon–carbon bond is part of a cyclopropane ring system. In fact, a cyclopropane group attached to a carbonyl group is often used to probe the mechanism of SmI_2 -mediated reactions: if a ketyl radical anion is formed during the reaction, fragmentation of the three-membered ring occurs rapidly.^{75,76} These fragmentation processes proceed via Sm(III) enolate/radical intermediates that can be trapped. For example, Motherwell has shown that the Sm(III) enolates/radicals resulting from ketone reduction

Scheme 15 Ketone reduction and fragmentation.

and cyclopropane fragmentation can be quenched by radicophiles or electrophiles.⁷⁷ Treatment of cyclopropyl ketone **33** with SmI_2 gave bicyclic ketone **34** from interception of an intermediate radical, while exposure of cyclopropylketone **35**

to the reagent gave **36** after quenching of the Sm(III)-enolate intermediate with allyl bromide (Scheme 15).⁷⁷

4.3 Reduction of Carboxylic Acids, Esters, and Amides Using SmI₂

While SmI₂ has been used to partially reduce α -heteroatom-substituted esters, lactones, and amides (see Section 4.4), the reduction of simple unfunctionalized substrates is not usually possible. It is now clear that in certain cases reduction using SmI₂ is possible provided an activating additive is used. For example, Kudo reported the reduction of carboxylic acids with SmI₂, H₂O, and NaOH,⁷⁸ and the reduction of aryl acids, esters, and amides using SmI₂ and H₂O.⁷⁹ The H₂O cosolvent is known to activate SmI₂ (Section 2) and its inclusion is crucial to the success of these reductions.

More recently, Procter has shown that unfunctionalized lactones can be reduced using SmI₂-H₂O.^{37,38,64} The reagent system is selective for the reduction of lactones over esters; furthermore, it displays ring-size selectivity in that six-membered lactones are most readily converted

to the corresponding diols (Scheme 16). Procter has also shown that SmI₂-H₂O can be used for the selective monoreduction of cyclic 1,3-diester (Scheme 16).^{63,80}

Recently, Markó used the SmI₂-mediated reduction of aryl esters in a new deoxygenation protocol.⁸¹ Reduction of primary, secondary, and tertiary toluates using SmI₂-HMPA at reflux in THF (or THP) gave the corresponding deoxygenated products via ketyl radical anions **37** (Scheme 17).⁸¹

4.4 Reduction of α -Heteroatom-Substituted Carbonyl Groups Using SmI₂

The reduction of α -heteroatom-substituted carbonyl compounds to the parent carbonyl compound is a common use for SmI₂. A range of heteroatom substituents can be removed efficiently in the presence of a range of other functional groups, and the Sm(III) enolates generated can be used in C-C bond-forming reactions (Section 9).

The mechanism of reduction is thought to proceed via ketyl radicals **38** and carbanions **39**, which undergo β -elimination to produce Sm(III) enolates that are then protonated (Scheme 18).⁸² In some

Scheme 16 Lactone and cyclic 1,3-diester reduction.

Scheme 17 Aryl ester reduction and fragmentation.

Scheme 18 Reduction of α -heteroatom substituted carbonyl compounds.

cases, electron transfer to the α -substituent generating a radical anion intermediate and fragmentation may provide an alternative mechanism not involving carbonyl reduction (Scheme 18).⁸³

Molander has shown that a range of α -oxy, α -halo, and α -sulfanyl ketones undergo efficient conversion to the parent ketones with no over-reduction of the ketone carbonyl.⁸³ α,β -Epoxy ketones and 2-acylaziridines are also

reduced to give β -hydroxy and β -amino ketones, respectively.^{84,85} α -Heteroatom-substituted esters, lactones, and amides can also be partially reduced to the parent carbonyl compound using SmI_2 although activating additives are required.^{85–88} Recently, the defluorination of esters and amides using the $\text{SmI}_2\text{--Et}_3\text{N--H}_2\text{O}$ reagent system has been described (Scheme 19),⁸⁹ and the use of SmI_2 for the reductive carbon–nitrogen bond cleavage

Scheme 19 Partial reduction of α -heteroatom-substituted carbonyl compounds.

Scheme 20 Chemoselective reduction of an α -heteroatom-substituted ketone.

of α -amino carbonyl compounds has recently been reviewed.⁹⁰

The chemoselectivity of SmI_2 in this transformation is highlighted in Holton's one-step synthesis of 10-deacetytaxol **41** from Taxol® **40** (Scheme 20).⁹¹

Procter has applied the reduction of α -heteroatom-substituted amides in a linker strategy for solid-phase and fluorous synthesis (Scheme 21).⁷⁶

The reduction of α -heteroatom-substituted carbonyl compounds with SmI_2 has been used to

trigger elimination and the selective synthesis of α,β -unsaturated esters and amides.^{68,92,93}

4.5 Reduction of Nitrogen-Containing Compounds

In Kagan's early investigations, it was shown that nitroarenes could be reduced to the corresponding anilines using SmI_2 .⁹⁴ Subsequently, Kende showed that primary, secondary, or tertiary nitroalkanes could also be reduced using SmI_2 to the corresponding hydroxylamines or amines, depending on the amount of reagent used.⁹⁵ SmI_2 can reduce N–O bonds in many other substrates including hydroxamic acid derivatives,⁹⁶ pyridine *N*-oxides,⁹⁷ isoxazoles,⁹⁸ and isoxazolines,^{99,100} often when the use of other reagents prove unsuccessful (Scheme 22).

Since Kagan's first report of N–N bond reduction using SmI_2 ,⁹⁴ the reagent is now routinely used for the transformation. For example, the reaction has been used widely in asymmetric synthesis to reduce the products of asymmetric additions to, or reductions of,¹⁰¹ hydrazone derivatives. Selected examples include the reduction of (*S*)-1-amino-2-methoxymethylpyrrolidine (SAMP) and (*R*)-1-amino-2-methoxymethylpyrrolidine (RAMP) hydrazones,¹⁰² and the reduction of activated N–N bonds in adducts resulting from asymmetric allylation¹⁰³ and organocatalytic α -amination¹⁰⁴ (Scheme 23).

Scheme 21 Linker strategy involving the reduction of α -heteroatom-substituted amides.

Scheme 22 Examples of N–O bond cleavage.

Scheme 23 Reduction of N–N bonds.

4.6 Reduction of Electron-Deficient Alkenes

In the early 1990s, Inanaga and Alper independently reported the conjugate reduction of α,β -unsaturated esters and amides with SmI_2 , activated by the additives *N,N*-dimethylacetamide (DMA) and HMPA, respectively.^{105,106} The reduction of electron-deficient alkenes in lactones and cyclic enones using SmI_2 is also possible.¹⁰⁷ More recently, the use of the SmI_2 – H_2O –amine system has been shown to be effective for the selective reduction of α,β -unsaturated esters and conjugated double and triple bonds.^{43,108} Keck utilized SmI_2 to reduce an electron-deficient alkene in an approach to the marine natural product dolabelide B.¹⁰⁹ Treatment of α,β -unsaturated ester **42** with SmI_2 in the presence of MeOH and DMA gave **43** in moderate yield (Scheme 24).

The reduction of electron-deficient alkenes is thought to proceed through radical enolate species **44**. Further reduction generates dianionic species **45**, which undergo stepwise protonation to give

the product of reduction via Sm(III) enolates (Scheme 25).

4.7 Reduction of Sulfur-Containing Compounds

Sulfoxides are reduced to sulfides by SmI_2 activated by HMPA.¹¹⁰ The reduction of sulfones with SmI_2 can result in deoxygenation, to give the parent sulfide,¹¹⁰ or carbon–sulfur bond cleavage, depending on the substrate and the reaction conditions employed.¹¹¹ Gin has utilized the reduction of an alkyl phenyl sulfone in a recent synthesis of the anti-leukemia natural product (–)-deoxyharringtonine.¹¹² Treatment of complex sulfone **46** with SmI_2 –HMPA gave **47** in 74% yield (Scheme 26).

The most important application of sulfone reduction using SmI_2 is in the modified Julia–Lythgoe olefination.¹¹³ Fukumoto¹¹⁴ and Keck²⁹ independently reported the use of SmI_2 –HMPA and SmI_2 –DMPU, respectively, in olefination processes

Scheme 24 Conjugate reduction in natural product synthesis.

Scheme 25 Mechanism of conjugate reduction.

Scheme 26 Sulfone reduction in natural product synthesis.

involving phenylsulfones. Both approaches are selective for the formation of *E*-alkenes. The use of SmI_2 shows considerable advantages over the use of Na-Hg in the classical olefination (Scheme 27). More recently, Markó has used SmI_2 to reduce β -benzoyloxy sulfones¹¹⁵ and sulfoxides¹¹⁶ in modified Julia–Lythgoe olefinations.

5 PINACOL COUPLINGS

The reductive coupling reaction between two carbonyl compounds represents an important synthetic tool for the preparation of carbon–carbon bonds.^{117–121} Typically, low-valent metals or metal complexes promote these reactions and it is well accepted that metal ketyl radical anions are intermediates. Owing to the ease with which the reagent is prepared and used, and the high yields that are often obtained, SmI_2 has become one of the most popular reagents for mediating pinacol couplings (Scheme 28).

Although the precise mechanism for SmI_2 -mediated pinacol couplings is not fully known, there are three possible pathways depending on the character of the carbonyl functionality undergoing reductive coupling and whether the reaction is intra- or intermolecular (Scheme 29). An initial reduction step involving a rapid and reversible inner-sphere electron transfer from Sm(II) to the C=O bond resulting in the formation of the Sm(III) -bound ketyl radical anion is common to all three mechanisms. If the carbonyl group is easily reduced, then a high concentration of the ketyl is generated, leading to dimerization (Path A). This mechanism is believed to operate for the intermolecular coupling of aldehydes and activated ketones.

In Path B, a second electron transfer reduces the ketyl radical anion, generating a dianionic intermediate that adds to a second equivalent of carbonyl substrate. Finally, the ketyl radical anion may undergo radical addition to the carbonyl group of a

Scheme 27 Sulfone reduction in the Julia–Lythgoe olefination.

Scheme 28 Intermolecular pinacol coupling.

second equivalent of substrate, generating a highly reactive oxy radical species (Path C). Although this addition is typically unfavorable, activation of the carbonyl substrate by the Lewis acidic Sm(III) center of the ketyl radical anion and rapid reduction of the highly reactive oxy radical intermediate by SmI₂, resulting in the formation of a stable Sm(III) complex, would facilitate the addition.

Path C explains why α -heteroatom-substituted carbonyl compounds undergo intramolecular pinacol couplings without cleavage of the α -heteroatom substituent: Pinacol cyclization is faster than

the reduction of the ketyl radical anion to the corresponding anion. Furthermore, coordination of Sm to the second carbonyl group after the first electron-transfer step, explains the selectivity for *cis*-diol formation in five- and six-membered ring synthesis.

5.1 Intermolecular Pinacol Couplings

SmI₂ promotes the intermolecular reductive dimerization of aldehydes or ketones giving rise to diols.^{122–124} Although aryl aldehydes and ketones often react rapidly, aliphatic aldehydes and ketones can react more slowly and the addition of activating additives such as HMPA is required.²¹ In most cases, particularly with simple aldehydes, both the threo- and erythro-diols are

Scheme 29 Alternative mechanisms for pinacol coupling.

formed, with low stereocontrol.¹²⁵ However, strategies are available to improve the levels of stereoselectivity observed in SmI_2 -promoted pinacol couplings. For example, Skrydstrup has reported that the use of tetraglyme and its derivatives as additives can increase diastereoselectivities while maintaining good coupling yields (Scheme 30).^{125,126}

Uemura has demonstrated that enantiomerically pure (arylaldehyde)tricarboxylchromium complexes afford exclusively the threo-pinacols, providing an asymmetric synthesis of hydrobenzoin.¹²⁷ In 1996, Endo reported a protocol for pinacol coupling using catalytic amounts of SmI_2 with magnesium as the stoichiometric reductant and tetramethylsilyl chloride (TMSCl) to liberate Sm(III) from the pinacolate. The method provides good yields of the vicinal diol products and employs only 10 mol% of SmI_2 (Scheme 31).¹²⁸ Greeves and Aspinall later modified this protocol by using Me_2SiCl_2 as the chlorosilane and tetraglyme as an additive to improve the diastereoselectivity of the reductive couplings.¹²⁹

Scheme 30 Intermolecular pinacol couplings of aldehydes.

Scheme 31 Pinacol couplings using catalytic SmI_2 .

The use of this protocol provided good to excellent diastereoselectivities in a range of intermolecular and intramolecular pinacol coupling reactions. Coordination of glyme to both Sm(II) and Sm(III) is believed to be important in enhancing the diastereoselectivity of the pinacol couplings as well as facilitating the reduction of Sm(III) to Sm(II) .¹²⁹

5.2 Intramolecular Pinacol Couplings

In contrast to intermolecular couplings, high levels of diastereoselectivity can be attained in the cyclization of a variety of 1,5- and 1,6-dicarbonyl

Scheme 32 Diastereoselective, intramolecular pinacol coupling.

Scheme 33 Chelation control in diastereoselective intramolecular pinacol couplings.

substrates, leading almost exclusively to the formation of *cis*-vicinal diols. Electron-withdrawing substituents α to the reacting carbonyl can act as controlling elements and the *cis*-1,2-diol forms anti to the substituent in the product. For example, Iadonisi reported an intramolecular SmI₂-promoted pinacol coupling of the keto-aldehyde **48** leading

to the *cis*-diol **49** with high diastereocontrol in the synthesis of caryose (Scheme 32).¹³⁰

Chelation to a neighboring Lewis basic carbonyl can also control the diastereoselectivity of pinacol cyclizations. For example, cyclization of ketoester **50** proceeds with high diastereocontrol to give *cis*-diol **51** (Scheme 33).^{131,132} The application of

Scheme 34 Effect of substituents on the diastereoselectivity of pinacol cyclization.

Scheme 35 Intramolecular pinacol couplings in natural-product synthesis.

analogous chelation control in six-membered ring formation is less effective.

The stereochemical outcome of SmI_2 -mediated pinacol couplings to form six-membered rings is also dependent on neighboring substituents. For example, in d'Alarcao's studies on the synthesis of the myo-inositol derivative **55**, non- C_2 -symmetrical dialdehyde **52** underwent reductive cyclization on treatment with SmI_2 to give *cis*-diol **53** via transition state structure **54** (Scheme 34).¹³³

The intramolecular SmI_2 -mediated pinacol coupling has been exploited for the construction of different ring sizes in many natural product syntheses. A selection of applications is shown in Scheme 35.¹³⁴

5.3 Pinacol Couplings of Imines and Their Equivalents

Pinacol couplings in which one of the coupling partners is an imine derivative are useful for the construction of vicinal amino alcohols. Oximes and hydrazones undergo *heteropinacol* cyclizations resulting in five- to seven-membered carbo- and heterocycles. In contrast to analogous pinacol cyclizations of dicarbonyl compounds, trans products are often the major products formed from heteropinacol

Scheme 36 Heteropinacol couplings in natural product synthesis.

cyclizations.^{135,136} As oximes and hydrazones are not easily reduced, the mechanism for these reactions most likely involves addition of a ketyl radical anion to the $\text{C}=\text{N}$ double bond.

Naito¹³⁷ and Skrydstrup¹³⁸ have reported the stereoselective synthesis of the azepine ring of the protein kinase C (PKC) inhibitor balanol using a heteropinacol cyclization (Scheme 36).

Nicolaou used an aldehyde–oxime coupling to construct the 12-membered macrocyclic core of diazonamide A in an impressive total synthesis of the complex natural product (Scheme 37).^{139,140}

Analogous intermolecular couplings have only recently been shown to be a viable strategy for the preparation of vicinal amino alcohols. In 2002,

Scheme 37 Heteropinacol coupling in the synthesis of diazonamide A.

Scheme 38 Intermolecular heteropinacol couplings of nitrones.

Py and Vallée described the intermolecular heteropinacol couplings of nitrones with aldehydes and ketones, generating *N*-hydroxyamino alcohols (Scheme 38).^{141,142} More recently, Huang described the use of chiral nitrones in SmI_2 -mediated reductive couplings with aldehydes, ketones, and acyl chlorides.¹⁴³

Intramolecular carbonyl–nitron couplings have been studied and, after concurrent N–O bond reduction with excess SmI_2 , provided *syn*-amino alcohols, thereby complementing analogous anti-selective cyclizations of oximes and hydrazones.¹⁴¹ In nitron–carbonyl couplings, a mechanism in which the nitron is preferentially reduced to a ketyl radical anion-like intermediate followed by addition to the carbonyl is likely to operate.

Although Uemura has reported the stereoselective heteropinacol coupling of planar chiral ferrocenecarboxaldehydes with imines,¹⁴⁴ stereoselective intermolecular heteropinacol couplings have only recently been developed.¹⁴⁵ Xu has shown that the SmI_2 -induced reductive coupling of *N*-*t*-butylsulfinyl imines with aliphatic aldehydes provides the pinacol products in high yield and with excellent diastereoselectivity (Scheme 39).

Xu has also developed asymmetric approaches to vicinal diamines via the homo- and cross-pinacol coupling of imine derivatives. Reductive homocoupling of aryl *N*-*t*-butylsulfinyl imines upon treatment with SmI_2 –HMPA gave C_2 -symmetrical vicinal diamines as single stereoisomers after removal of the sulfinyl groups from nitrogen

Scheme 39 Intermolecular heteropinacol couplings with *N*-*t*-butylsulfinyl imines.

Finally, Skrydstrup has reported that five-membered ring systems containing *cis*-diamine motifs can be prepared using a SmI_2 -mediated reductive cyclization of dinitrones.¹⁴⁸ The couplings show similarities to intramolecular pinacol couplings in that syn-products predominate (Scheme 41).

6 CARBONYL-ALKENE COUPLINGS

Electron-deficient olefins represent the best coupling partners in intermolecular SmI₂-promoted carbonyl–alkene couplings. These reactions have been described as ketyl–olefin couplings in which a ketyl radical anion is generated from the carbonyl substituent followed by addition to the unsaturated C–C bond. Subsequent reduction of the new radical intermediate leads to a Sm(III) enolate or enolate-type species, which abstracts a proton from an acidic source (Scheme 42). An alternative mechanism involving conjugate reduction of the double bond followed by anionic (or possibly radical) addition to the carbonyl group may also operate when electron-deficient alkenes are involved (Scheme 42).

Procter has suggested that a study of the dependency of reaction outcome on the stereochemistry of the double bond in the alkene can be used to gain information on the mechanistic "direction" of reductive couplings.^{34,149} In cases where the alkene stereochemistry has a marked effect on the reaction outcome, a traditional "carbonyl first" mechanism may be in operation, whereas in reactions where alkene stereochemistry has little effect, an alternative mechanism in which the alkene is

Scheme 42 Mechanisms of carbonyl–alkene coupling.

reduced first and a common reactive intermediate is formed, regardless of the geometry of the starting alkene, may operate.^{34,149}

In contrast to *intermolecular* carbonyl–alkene couplings, *intramolecular* variants tolerate a wide range of radical acceptors including unactivated alkenes. In these cases, the reactions must proceed through the “traditional” pathway, as the alkene cannot be reduced under the reaction conditions.

6.1 Intermolecular Carbonyl–Alkene Couplings

Essentially all carbonyl–alkene coupling reactions require the presence of an alcohol proton source for high yields to be obtained. Although the additive can perform different functions in these reactions (see

Section 2), one important role of the alcohol additive is to quench anionic intermediates. The addition of HMPA accelerates couplings by the generation of a more powerful reducing agent.¹⁵⁰

Fukuzawa and Inanaga showed that the coupling of ketones and aldehydes with acrylates mediated by SmI_2 often gives γ -lactones after cyclization of the intermediate alkoxide produced from the carbon–carbon bond-forming step (Scheme 43).^{150–152} The inclusion of a chelating α -substituent in the ketone component has been shown to induce high levels of asymmetric induction in the formation of adducts (Scheme 43).¹⁵³

In 1997, Fukuzawa reported the asymmetric synthesis of γ -lactones by reductive coupling of aldehydes and ketones with acrylates and crotonates bearing the chiral auxiliary *N*-methylephedrine (Scheme 44).¹⁵⁴ This reaction has been used

Scheme 43 Intermolecular carbonyl–alkene couplings.

Scheme 45 Reductive coupling of ketones with acrylates.

Scheme 44 Asymmetric intermolecular carbonyl–alkene couplings.

A range of alkenes bearing other chiral auxiliaries¹⁵⁸ and enantiomerically pure aryl aldehyde:Cr(CO)₃ complexes have been used in analogous asymmetric couplings.¹⁵⁹

In a seminal study on the development of a catalytic SmI₂ reagent system, Corey showed that the combination of SmI₂, LiI, and Me₃SiOSO₂CF₃ (TMSOTf) with Zn–Hg gave excellent results in the reductive coupling of ketones with acrylates to produce γ -butyrolactones (Scheme 45).¹⁶⁰

6.2 Intramolecular Carbonyl–Alkene Couplings

Intramolecular carbonyl–alkene couplings have been used to prepare a wide range of carbo- and heterocyclic systems of varying ring size and are tolerant of several types of acceptors, including

by Procter in solid-phase and fluororous asymmetric catch-and-release approaches to γ -lactones using acrylates and crotonates and a chiral linker (Scheme 44).^{155–157}

Scheme 46 Intramolecular carbonyl–alkene couplings.

unactivated alkenes. Good levels of diastereocontrol are typically observed in these cyclizations.

The cyclization of isolated ketones onto unactivated alkenes represents the most straightforward carbonyl–alkene cyclization. In common 5-*exo*-cyclizations, stereoselectivities depend markedly on the substituent on the ketone (Scheme 46).¹⁶¹ HMPA is used to allow the ketyl additions to proceed at a satisfactory rate. The outcome of 5-*exo*-carbonyl–alkene cyclizations can be explained by invoking a chair-like anti-transition structure.¹⁶¹ Increasing the size of the ketone can lead to a reversal of diastereoselectivity.

High levels of diastereoselectivity are also commonly observed for 5-*exo*-cyclizations leading to both fused and bridged bicyclic ring systems.^{161,162}

Alkynes can also be used as radical acceptors for the generation of cyclopentanols bearing an exocyclic alkene, but yields are often lower than those obtained in the related cyclizations of alkenes. Activation of the alkynes by electron-withdrawing groups or silyl substituents leads to more efficient 5-*exo*-dig ring closure.¹⁶³ Molander has demonstrated that 5-*exo*-transannular reductive carbonyl addition to an endo- or exocyclic alkene can be highly effective for the formation of bicyclic ring systems.¹⁶⁴

The presence of a proximal carbonyl group that can coordinate to Sm(II) and Sm(III) is advantageous, as HMPA is not required to promote reduction (the electron-withdrawing nature of the substituent lowers the lowest unoccupied

Scheme 47 Chelation control in a carbonyl–alkene cyclization.

molecular orbital (LUMO) of the carbonyl) and chelation of the Sm(III) in the ketyl intermediate to the group leads to high diastereoselectivity (Scheme 47).¹³²

In addition to the popular five-membered ring-forming reactions with non-activated alkenes, the 6-*exo* variant has been used to generate cyclohexanols and bicyclic alcohols.^{161,162} Molander has also described unusual 8-*endo* cyclizations.¹⁶⁵ The ability of SmI₂ to promote the formation of medium-sized rings can be attributed to the high steric bulk of the alkoxy-samarium–HMPA substituent that protects the radical anion from alternative reaction pathways such as hydrogen abstraction. Molander has exploited an 8-*endo* cyclization in the synthesis of (+)-isochizandrin (Scheme 48).¹⁶⁶

The use of electron-deficient olefins in these cyclization reactions has been widely studied and a variety of cyclic systems have been prepared. In most cases, the use of HMPA is not necessary for achieving high conversions, and chelation control can therefore lead to products with high diastereoselectivity. For example, Weinges and Procter have reported an efficient 4-*exo* cyclization of γ,δ -unsaturated aldehydes to give

anti-cyclobutanols in good yield (Scheme 49).^{167–169} The cyclization has been employed by Procter in an approach to the natural product pestalotiopsin A.¹⁷⁰

Carbonyl–alkene additions are also effective for the diastereoselective construction of oxacyclic ring systems. Nakata has shown that even the formation of seven-membered cyclic ethers using the transformation can be efficient and has

Scheme 50 Heterocycle formation using a carbonyl–alkene cyclization.

Scheme 48 8-*endo* Carbonyl–alkene cyclization in natural product synthesis.

Scheme 49 4-*exo*-Carbonyl–alkene cyclizations.

Scheme 51 Cyclizations involving alkenes with allylic leaving groups.

Scheme 52 Carbonyl–arene cyclizations.

utilized the strategy to form the E ring of the polycyclic ether marine natural product yessotoxin (Scheme 50).¹⁷¹

An alternative means of promoting carbonyl–alkene cyclizations is to use an alkene-activating

group that is removed spontaneously after cyclization by elimination from an organosamarium intermediate. Allylic sulfides,¹⁷² acetates,¹⁶⁵ and chiral acetals,¹⁷³ have been employed in carbonyl–alkene cyclizations (Scheme 51).

6.3 Carbonyl–Arene Couplings

In addition to alkenes, arenes can sometimes be used as radical acceptors in carbonyl–alkene couplings. Studies carried out by Reissig have demonstrated the utility of these reactions for the synthesis of polycyclic systems.¹⁷⁴ For example, cyclizations of naphthyl ketones,¹⁷⁴ indolo ketones,^{175,176} and pyrrolo ketones¹⁷⁶ proceed in good yield and often with high levels of diastereocontrol (Scheme 52).

6.4 Reductive Couplings of Imines and Their Equivalents

Imine equivalents have recently been used in place of the carbonyl component in reductive couplings with alkenes. In particular, Py and Skrydstrup have shown that nitrones are excellent coupling partners in intermolecular reactions. In their work on the asymmetric synthesis of γ -amino acids, Skrydstrup studied the reductive coupling

of nitrones and α,β -unsaturated esters bearing a chiral auxiliary (Scheme 53).¹⁷⁷ Py has used a nitron–alkene coupling in a short, asymmetric synthesis of (+)-hyacinthacine A₂ (Scheme 53).¹⁷⁸ Finally, Ellman has reported a sulfinimine–alkene coupling mediated by SmI₂ in the total synthesis of the anticancer agent tubulysin D (Scheme 53).¹⁷⁹

The use of a nitron in couplings with alkenes provides an alternative approach for asymmetric control through the attachment of a chiral auxiliary to the nitrogen of the nitron. Carbohydrate-based auxiliaries and the 1-(triisopropylphenyl)ethyl auxiliary group have been developed by Skrydstrup¹⁸⁰ and Py,^{181,182} respectively, for asymmetric reductive couplings.

6.5 Ester Carbonyl–Alkene Cyclizations

Procter has recently shown that the use of H₂O as an additive allows some ester carbonyls to be reduced by one electron and that the resultant radical anions

Scheme 53 Nitron and sulfinimine–alkene couplings.

can undergo intramolecular coupling with pendent alkenes (Scheme 54).^{37,38,63,64,80}

7 RADICAL ALKENE–ALKYNE ADDITIONS

7.1 Introduction

SmI_2 also mediates the addition of sp^3 or sp^2 carbon-centered radicals, typically formed from halides or sulfones, to carbon–carbon multiple bonds. In the majority of these cyclizations, the radical acceptors are unactivated alkenes and alkynes, but activated radical acceptors including α,β -unsaturated amides, esters, nitriles, lactams, and lactones have also been employed. Although tributyltin hydride can be used to mediate such reactions, the use of SmI_2 requires lower reaction temperatures and the lanthanide salt by-products are less toxic and are easily separated from products. However, as the reducing conditions used to generate an alkyl radical will also reduce the radical to the corresponding organosamarium, for successful ring closure the unimolecular rate constant for cyclization (k_{cyc}) must be higher than the bimolecular rate constant for the second reduction step multiplied by the SmI_2 concentration ($k_{\text{red}} \cdot [\text{SmI}_2]$).⁵⁶ Performing the reactions at low substrate concentration is a common

Scheme 55 Cyclization versus over-reduction of alkyl halides.

strategy to reduce the chance of organosamarium formation prior to cyclization (Scheme 55).

The 5-*exo*-trig and 5-*exo*-dig radical cyclizations represent the most successful classes of SmI_2 -mediated radical-alkene/alkyne cyclizations.

7.2 Radical Additions to Alkenes

Alkyl radicals generated from the reduction of halides or sulfones with SmI_2 have been successfully exploited in intramolecular additions to alkenes to form small carbocyclic and heterocyclic ring systems. Substrates containing an oxygen atom within

Scheme 56 Radical-alkene cyclizations to form heterocycles.

Scheme 57 Radical-alkene cyclization in the formation of a C-disaccharide.

the tether linking the radical and the alkene undergo particularly successful 5-*exo*-trig cyclizations. For example, Fukuzawa has shown that unsaturated alkyl halides, such as **56**, undergo efficient cyclization in an efficient two-step synthesis of γ -lactones (Scheme 56).¹⁸³

Scheme 58 Radical-alkene cyclizations with electron-deficient alkenes.

Analogous cyclizations of glycosyl sulfones have been exploited in the stereoselective synthesis of C-glycosides. For example, Sinay reported that slow addition of SmI₂ in benzene and HMPA to glycosyl sulfone **57** bearing a tethered unsaturated sugar triggered a 9-*endo* radical cyclization to give **58**. Subsequent desilylation of the major C4-epimer **58** provided the disaccharide mimic **59** in an overall yield of 50% (Scheme 57).¹⁸⁴

Electron-deficient alkenes, such as α,β -unsaturated esters and amides (and alkynes), can also be exploited in SmI₂-mediated radical cyclizations. For example, Molander has shown that yields and selectivities often exceed those obtained in similar radical cyclizations using alternative reagents (Scheme 58).⁴⁸ These additions typically require an alcohol additive to quench the enolates

Scheme 59 sp^3 -Radical-alkene cyclization in natural-product synthesis.

that result from the addition and the use of NiI_2 as an additive has a beneficial effect.

Bennett has shown that sugar-derived substrates can also be used for the preparation of highly functionalized cyclopentanes.^{185,186} Procter has employed a highly diastereoselective SmI_2 -mediated intramolecular 1,4-addition during studies on the synthesis of faurinone: treatment of iodide **60** with SmI_2 in THF–HMPA gave *cis*-hydrindane **61** in good yield (Scheme 59).^{187,188}

N -[(N',N' -Dialkylamino)alkenyl]benzotriazoles have been shown to be useful precursors to α -amino radicals in 5-*exo*- and 6-*exo* ring closure onto α,β -unsaturated esters or nitriles.¹⁸⁹

Aryl halides have been widely exploited in 5-*exo*-trig and 6-*exo*-trig radical cyclizations. For example, Lu and Cai reported a synthesis of the natural products cryptotanshinone and tanshinone IIA, in which the dihydrofuran ring in the intermediate **63** was installed using a SmI_2 -mediated cyclization of the aryl bromide **62** (Scheme 60).¹⁹⁰

Scheme 60 sp^2 -Radical-alkene cyclization in natural-product synthesis.

7.3 Radical Additions to Alkynes

Carbon-centered radicals formed from halides using SmI_2 undergo 5-*exo*-dig additions to alkynes to give cyclic systems bearing exomethylene substituents. The alkenyl radicals formed after ring closure can abstract a hydrogen atom from the solvent if they are unstable, or can be reduced to the corresponding anion if they are stabilized by neighboring groups.^{191–193} Ohta has exploited 5-*exo*-dig cyclizations in approaches to the natural products oxerine and pyrrolam A (Scheme 61).^{194,195}

Aryl and alkenyl radicals also undergo cyclizations onto alkynes. Such ring closures are less efficient than examples involving sp^3 -carbon-centered radicals. Inanaga and Molander reported the application of aryl halide-alkyne cyclizations in the construction of the indole and naphthafuran frameworks using SmI_2 in THF–HMPA (Scheme 62).^{196,197}

8 SAMARIUM DIODIDE-MEDIATED BARBIER AND GRIGNARD REACTIONS

The reduction of alkyl halides with SmI_2 generates radicals which are reduced further by SmI_2 to give organosamarium intermediates. These intermediates add to carbonyl groups in reactions that are referred to as *SmI₂-mediated Barbier or Grignard reactions*.¹⁹⁸ Both intra- and intermolecular couplings can be carried out efficiently to yield products

Scheme 61 Radical-alkyne cyclizations in natural-product synthesis.

Scheme 62 sp^2 -Radical-alkyne cyclizations.

that can be difficult to access using more traditional methods.

Barbier reactions refer to procedures in which a mixture of the alkyl halide and carbonyl compound is treated with SmI_2 , whereas Grignard reactions involve the treatment of the alkyl halide with SmI_2 prior to the addition of the carbonyl compound. As organosamariums are formed from radical intermediates, competing radical processes may be problematic if they proceed faster than the reduction of the intermediate radical to the organosamarium. In general, Barbier conditions should be used when the organosamarium intermediate is prone to dimerization (e.g., allylic and benzylic organosamariums), decomposition (e.g., by elimination), or self-condensation. Grignard conditions suit reactions in which the carbonyl compound may be reduced faster than the alkyl halide, thereby

leading to competing reactions (e.g., aryl ketones and aldehydes).¹⁹⁸

In contrast to Barbier reactions mediated by other metals (e.g., Mg, Li, Zn), the SmI_2 -mediated Barbier reaction is homogeneous and often highly chemoselective, and, in general, organosamarium reagents undergo 1,2-addition to enones rather than 1,4-addition unless their reactivity is modified by transmetallation.¹⁹⁹

The expected order of reactivity is observed in SmI_2 -mediated Barbier and Grignard reactions ($\text{RI} > \text{RBr} \gg \text{RCl}$): alkyl iodides and bromides undergo facile reaction, whereas alkyl chlorides typically do not react (allylic chlorides react slowly).¹³

SmI_2 -mediated Barbier reactions are typically carried out in THF with additives such as HMPA,^{21,26,200} NiI_2 ,^{47,201,202} or ferric salts such as $\text{Fe}(\text{DBM})_3$ [dibenzoylmethido (DBM)].^{13,47,203} The role of metal salt additives is not yet clear.^{52,201,202,204} Although primary, secondary, allylic, and benzylic halides can be used in the transformation in THF, the use of THF as solvent is often beneficial.^{55,67,205} Generally, benzene is used as the solvent for SmI_2 -HMPA reactions employing aryl, vinyl, and alkynyl halides, in order to avoid hydrogen atom abstraction from THF by the intermediate radicals.^{55,67} Light activation has also been used to increase the rate of reactions.^{201,202} Table 1 summarizes the additives, solvents, and carbonyl electrophiles typically employed in SmI_2 -mediated Barbier reactions for particular classes of alkyl halide.

Table 1 Summary of the additives and solvents used in Barbier additions.

Alkyl halide (or equivalent)	Additives	Solvent	Carbonyl electrophile
Alkyl iodide	None, HMPA Fe(III), Ni(II)	THF	Aldehydes, ketones, esters, amides, imides, nitriles
Alkyl bromide	None, HMPA	THF	Aldehydes, ketones, esters, amides (imides)
Alkyl chloride	HMPA, Fe(III), Ni(II) and $h\nu$	THF	Aldehydes, ketones (esters)
Alkyl tosylate	NaI	THF	Aldehydes, ketones
Allylic/benzylic iodide/bromide	None	THF, THP	Aldehydes, ketones
Allylic/benzylic chloride	none HMPA	THF, THP	Aldehydes, ketones (esters)
Aryl/vinyl/alkynyl halide	HMPA	Benzene, THF	Ketones (and aldehydes)

8.1 The Mechanism of SmI₂-Mediated Barbier and Grignard Reactions

SmI₂-mediated Barbier and Grignard reactions permit the coupling of alkyl halides and carbonyl compounds to give alcohols (or ketones if esters are employed as the electrophiles). Under Grignard conditions, the mechanism of intermolecular coupling has been shown to be straightforward: the alkyl halide is reduced by 2 equiv of SmI₂ to give organosamarium species that react with carbonyl electrophiles (Scheme 63).²⁰⁶ The organosamariums formed under Grignard conditions using SmI₂ are typically not long-lived and must be used quickly.

Determination of the mechanism of the intermolecular SmI₂-mediated Barbier reaction is more complex, as two reducible functional groups (the alkyl halide and the carbonyl group) are present in the reaction mixture with SmI₂. Curran proposed that the SmI₂-mediated Barbier reaction also involves the addition of an organosamarium, or carbanion, to a carbonyl group and this mechanism is widely accepted.^{67,206} With two reducible groups within the same molecule, the mechanism of the intramolecular SmI₂-mediated Barbier reaction is even less clear-cut and more difficult to investigate. Molander has produced evidence for the intermediacy of organosamarium species in these

processes,⁷⁵ and Curran has been integral in evaluating mechanistic evidence from Kagan's group and others.⁶⁷ However, despite extensive studies,²⁰⁷ the true nature of the SmI₂-mediated Barbier reaction has yet to be irrefutably elucidated; it now appears likely that the SmI₂-mediated Barbier reaction does not proceed by one discrete mechanism. In addition to substrate structure, many variables (including solvent, additives, and order of addition) may alter the reaction pathway.

8.2 Intermolecular SmI₂-Mediated Barbier and Grignard Reactions

In 1980, Kagan demonstrated the clear difference in behavior of primary, secondary, and tertiary alkyl halides in SmI₂-mediated Barbier reactions (Scheme 64).¹³ The use of SmI₂ to mediate such additions is noteworthy, since the reaction of *i*-BuMgBr or *s*-BuMgBr with ketones typically leads to reduction of the carbonyl group.

Kagan also showed that allylic, benzylic, and propargylic halides undergo efficient reaction with ketones.¹³ Importantly, in the absence of ketone, these alkyl halides react rapidly with SmI₂ to yield Wurtz homocoupled products; thus the use of Barbier conditions is crucial. Kagan later found

Scheme 63 Basic mechanism of Barbier and Grignard reactions mediated by SmI_2 .

^a Recovered ketone predominated.

Scheme 64 Primary, secondary, and tertiary alkyl halides in Barbier reactions.

that THF was a better solvent than THF for the generation and reaction of allylic and benzylic organosamariums.²⁰⁵ When THF is used, the allylation of aryl ketones (that are prone to pinacol coupling) is possible, provided Grignard conditions are employed, and ketones that are prone to enolization are efficiently allylated under Barbier conditions.²⁰⁵ Vinyl, alkynyl, and aryl halides are reduced by SmI_2 in THF to form radicals, but it is thought that the reaction does not proceed to form organosamariums because of competing radical processes.^{53,208} To prevent competing hydrogen-atom abstraction from THF, the reactions of iodobenzenes,⁵⁵ iodoalkynes,^{209,210} and vinyl halides²¹¹ have been carried out with SmI_2 –HMPA in benzene. In some cases, vinylsamarium reagents have been generated and used in THF.²¹²

A variety of functionalized organic halides may be employed in SmI_2 -mediated Barbier and Grignard reactions. For example, benzyloxymethyl chloride can be used in conjunction with SmI_2 for the alkoxymethylation of ketones (in contrast to analogous organometallics, decomposition via α -elimination is not observed).^{213,214} In addition, polyhaloalkanes such as iodoform, diiodomethane,²¹⁵ and diiodoethane,²¹⁶ as well as fluorinated alkyl halides,²¹⁷ have been used in SmI_2 -mediated Barbier and Grignard reactions (Scheme 65), and iodomethylations of ketones have also been carried out using mixtures of Sm and CH_2I_2 .²¹⁴

Scheme 65 Iodomethylations mediated by SmI_2 .

Although organosamariums can react with esters and lactones, they preferentially undergo addition to aldehydes or ketones, which allows ester-bearing organosamarium reagents to be employed in intermolecular Barbier couplings (Scheme 66).^{13,200} For example, Williams used SmI_2 to couple an aldehyde with a functionalized α -halo-2-methylazole (Scheme 66).²¹⁸

8.3 Intramolecular SmI_2 -Mediated Barbier Reactions

SmI_2 is the reagent of choice for the cyclization of a variety of halocarbonyl compounds,¹⁹⁸ giving cyclic systems, typically ranging in size from three- to nine-membered rings, often with high levels of diastereocontrol.^{219–222} The presence of

Scheme 66 Functional group tolerance in a Barbier addition.

ester and amide groups (α to the carbonyl group undergoing attack) in haloaldehyde and haloketone substrates can lead to high levels of diastereocontrol (Scheme 67). The syn-diastereoselectivity of these cyclizations most likely arises from kinetic control, in which chelation of Sm(III) to the 1,3-dicarbonyl controls the orientation of the carbonyl group prior to addition of the organosamarium.²²³

The SmI₂-mediated Barbier cyclization of alkyl halides bearing cyclic ketones has been used extensively to form bicyclic systems.²⁰³ When the alkyl halide tether is attached α to the cyclic ketone carbonyl, cyclization typically proceeds to give syn products. For example, treatment of bis-bromide **64** with SmI₂ in THF–HMPA gave diol **65** in 68% yield (Scheme 68).²²⁴

When the alkyl halide tether is not attached α to the cyclic ketone carbonyl group, SmI₂-mediated Barbier cyclizations result in bridged bicyclic systems. Molander found that these reactions were best carried out at low temperature in the presence of catalytic Fe(DBM)₃ (Scheme 69).⁷⁵

In the presence of catalytic Fe(III) salts, SmI₂ mediates intramolecular Barbier additions of alkyl and allylic halides to esters to give cyclic ketones (or cyclic hemiketals, if they prove to be stable).²²⁵ Reduction of the cyclic ketone product is not observed, suggesting that the tetrahedral intermediate (a samarium alkoxide of a cyclic hemiketal) is partially stable to the reaction conditions (Scheme 70).

As alkyl iodides and bromides are reduced faster by SmI₂ than alkyl chlorides, sequenced Barbier

Scheme 67 Chelation control in SmI₂-mediated Barbier additions.

Scheme 68 Double Barbier cyclization.

Scheme 69 Formation of strained bicyclics using Barbier cyclizations.

reactions involving dihaloester substrates are possible. For example, upon treatment of **67** under Molander's standard conditions, ketone **66** was obtained, whereas under more forcing conditions the alkyl chloride was also reduced, generating bicyclic alcohol **68** in good yield (Scheme 71).²²⁵

8.4 Intramolecular Barbier Additions to Imine Equivalents

Hydrazones^{136,226} and oximes^{227,228} are also effective participants in Barbier cyclizations. For example, treatment of the secondary iodide **69** with SmI_2 –HMPA gave cyclopentylhydrazine **70** with good diastereoselectivity (Scheme 72).^{136,226}

Scheme 70 Barbier addition to a lactone.

Scheme 71 Sequential Barbier reaction.

9 SAMARIUM DIIODIDE-MEDIATED REFORMATSKY AND ALDOL-TYPE REACTIONS

Sm(III) enolates can be exploited as nucleophiles in a number of reactions, although they behave differently to more conventional metal enolates.⁸² For example, there are few examples of the alkylation of Sm(III) enolates with alkyl halides. The reduction of α -heteroatom substituted carbonyl compounds is the most popular method for the generation of Sm(III) enolates, which can then be exploited as nucleophiles (e.g., they are known to undergo facile aldol reactions with aldehydes and ketones) or protonated to give the parent carbonyl compound. When the heteroatom substituent in the starting material is a halide, these reactions are commonly referred to as *SmI_2 Reformatsky reactions*, but it is important to recognize that these reactions are a subset of a much larger class of SmI_2 aldol-type reactions (Scheme 73).

The SmI_2 -mediated Reformatsky and aldol reactions can be used in inter- and intramolecular fashion and proceed under mild, homogeneous conditions. The high chemo-, regio-, and diastereoselectivity of these reactions offer considerable advantages over other metal-mediated reactions. The chemoselectivity of SmI_2 and the low basicity of the resultant Sm(III) -enolate species make the lanthanide reagent ideal for sensitive substrates. Although α -halo esters are the most common substrates for the reaction, in principle, any α -halo

Scheme 72 Barbier cyclizations of imine equivalents.

Scheme 73 SmI₂-mediated Reformatsky and aldol reactions.

Scheme 74 Early example of a SmI₂-mediated Reformatsky reaction.

carbonyl compound may be employed. The reactions are most often carried out by the addition of SmI₂ to a 1:1 mixture of the α -halocarbonyl compound and the coupling partner (*Barbier conditions*).

9.1 Intermolecular Reformatsky Reactions Using SmI₂

In 1980, Kagan reported the first example of a SmI₂-mediated Reformatsky reaction¹³ involving the coupling of ethyl α -bromopropionate with cyclohexanone (Scheme 74).

In the quest for an efficient catalytic SmI₂ reagent system, Namy has utilized mischmetal (La 33%, Ce 50%, Nd 12%, Pr 4%, Sm, and other lanthanides 1%) as the stoichiometric reductant for the regeneration of Sm(II) in several reaction types including Reformatsky reactions.^{229,230}

Analogous asymmetric SmI₂-mediated Reformatsky reactions of chiral 3-bromoacetyl-2-oxazolidinones have been described by Fukuzawa.²³¹ For example, reduction of **71** with SmI₂ generates a samarium enolate, which then reacts with pivalaldehyde to give β -hydroxy carboximide **72** in 87% yield and in high diastereoisomeric excess (Scheme 75).

As one would expect, coordination of the incoming electrophile to the Sm of the Sm(III)-enolate has an important influence on reactivity and diastereoselectivity in all SmI₂-mediated Reformatsky and aldol-type reactions. Lewis acid activation of the electrophile may explain why Sm(III)-enolate aldol-type reactions are relatively common while the reactions of Sm(III) enolates with alkyl halides are scarce.

Scheme 75 Asymmetric SmI_2 -mediated Reformatsky reaction.

The use of α -haloketones in intermolecular Reformatsky reactions²³² is less common and is typically restricted to simple coupling partners, presumably because the product ketones can undergo further reduction by SmI_2 . Similarly, the intermolecular Reformatsky reactions of α -haloamides have received little attention.^{233,234}

9.2 Intramolecular Reformatsky Reactions Mediated by SmI_2

Intramolecular SmI_2 -mediated Reformatsky reactions have been used to great effect, and often proceed with high levels of selectivity. Interestingly, there are several examples of intramolecular SmI_2 -mediated Reformatsky reactions that employ protic solvents. In fact, in some of these cases, alcohol cosolvents are essential for efficient cyclization.

Inanaga reported the use of SmI_2 -mediated intramolecular Reformatsky reactions to access medium- and large-ring lactones²³⁵ and carbocycles.²³⁶ For example, the cyclization of the Sm(III) -enolate intermediates **73** gave carbocycles **74** in good yield. Inanaga suggests that the successful formation of such rings is assisted by the large ionic radius of samarium, its flexible coordination number, and its high oxophilicity, the lanthanide center effectively bringing the two reacting centers together through chelation (Scheme 76).²³⁶

Molander showed that treatment of α -bromo esters such as **75** with SmI_2 resulted in a highly selective Reformatsky reaction to give lactones in excellent yield with high diastereoselectivity (Scheme 77).²³⁷

Scheme 76 Intramolecular Reformatsky reactions to access medium and large rings.

Scheme 77 Highly diastereoselective intramolecular Reformatsky reaction.

Scheme 78 Reformatsky cyclization to construct the B-ring of Taxol®.

Mukaiyama has used a SmI_2 -mediated Reformatsky cyclization to construct the B ring in an impressive total synthesis of Taxol® (Scheme 78).²³⁸

9.3 Intermolecular Aldol-Type Reactions Mediated by SmI_2

SmI_2 -mediated aldol-type reactions of other α -heteroatom-substituted carbonyl compounds in which the group expelled from the starting material is not a halogen (such as oxygen, nitrogen, sulfur, and selenium-containing substrates) are also possible.

For example, Procter reported that treatment of ketone **76** with SmI_2 in the presence of cyclohexanone or tetrahydropyran-4-one resulted in efficient aldol reaction to give adducts **77** and **78**,

respectively (Scheme 79). Here, DMPU is employed as an additive to increase the reduction potential of SmI_2 and to facilitate Sm(III) -enolate formation.⁷⁶

Skrydstrup has utilized the aldol reactions of Sm(III) enolates generated from 2-pyridylsulfides to introduce nonnatural carbinol side chains to glycine residues in small peptide substrates (Scheme 80).^{239,240}

SmI_2 -mediated aldol reactions can also be carried out using epoxides and aziridines as precursors to the Sm(III) -enolate.²⁴¹ Mukaiyama reported the use of SmI_2 to mediate aldol reactions between aldehydes and aryl/alkyl oxiranyl ketones, resulting in the synthesis of unsymmetrical bis-aldol products (Scheme 81), and also reported an intramolecular variant of this aldol process.²⁴² Mukaiyama has examined an asymmetric aldol process using an unsaturated aziridine bearing an Evans oxazolidinone auxiliary. For example, on treatment with

Scheme 79 Aldol-type reactions of α -aryloxy carbonyl compounds.

Scheme 80 Aldol-type reactions of Sm(III) enolates derived from 2-pyridylsulfanylamides.

Scheme 81 Aldol reactions between aldehydes and oxiranyl/aziridinyl ketones.

SmI₂, aziridine **79** underwent smooth ring-opening, Sm(III)-enolate formation, and a highly diastereoselective aldol process to give diastereoisomer **80** in good yield (Scheme 81).²⁴³

α -benzoyloxy esters, such as **81**, with SmI₂ led to the generation of a Sm(III)-enolate **82**, aldol cyclization, and addition of the resultant samarium alkoxide to the β -lactam carbonyl. The efficient sequential reaction gave proline derivatives, such as **83**, with high diastereoselectivity and in good yield (Scheme 82).²⁴⁴

9.4 Intramolecular Aldol-Type Reactions Mediated by SmI₂

Intramolecular SmI₂ aldol-type reactions involving α -heteroatom-substituted carbonyl compounds have also been reported. For example, Skrydstrup reported the diastereoselective construction of functionalized prolines using a SmI₂-mediated aldol cyclization.²⁴⁴ Treatment of β -lactam-derived

9.5 SmI₂-Mediated Aldol-Type Reactions as Part of Sequential Processes

Other substrates react with SmI₂ to form Sm(III) enolates that undergo aldol-type reactions as part of sequential processes. For example, the conjugate

Scheme 82 Intramolecular SmI_2 aldol-type reaction.

Scheme 83 Conjugate reduction/aldol cyclization.

Scheme 84 SmI_2 -mediated Reformatsky/nucleophilic acyl substitution.

reduction of α, β -unsaturated carbonyl compounds is a potentially useful way of accessing Sm(III) enolates, which has yet to be widely exploited. Procter has reported the diastereoselective spirocyclization of unsaturated ketones **84** using SmI_2 ,^{34,245} which proceeds by conjugate reduction, Sm(III) -enolate generation, and chelation-controlled aldol cyclization to give syn-spirocyclic cyclopentanols **85** in good yield (Scheme 83). The success of the reductive aldol cyclization relies on the protic cosolvent, which presumably promotes the conjugate reduction step.^{34,245} SmI_2 ketyl-olefin couplings also generate Sm(III) enolates that can

be exploited in Reformatsky/aldol processes (see Section 10).

Molander has developed a sequential SmI_2 -mediated Reformatsky nucleophilic acyl substitution reaction for the synthesis of medium-sized carbocycles²⁴⁶: Treatment of α -iodoester **86** with SmI_2 generates iodo-lactone **87**, which then undergoes nucleophilic acyl substitution to give **88** as a single diastereoisomer (Scheme 84). The NiI_2 catalyst promotes reduction of the intermediate alkyl iodide to the corresponding alkylsamarium required for nucleophilic addition to the lactone carbonyl.²⁴⁶

10 SEQUENTIAL CARBON–CARBON BOND-FORMING REACTIONS MEDIATED BY SAMARIUM DIODIDE

Sequential reactions in which a number of transformations convert simple starting materials to complex products using a single reagent in a single synthetic operation are the holy grail of the synthetic chemist. Of the many reducing agents available to the synthetic chemist, SmI_2 is the one reagent able to orchestrate powerful sequential carbon–carbon bond-forming processes often with exquisite control of structure and stereochemistry.^{191,204,247}

10.1 Sequences Initiated by Radical Cyclizations

10.1.1 Radical/Radical Sequences

Curran's elegant approach to the natural products ($\pm$)-hypnophilin and ($\pm$)-coriolin consists of a

5-*exo*-trig cyclization followed by a stereoselective 5-*exo*-dig cyclization in a radical/radical cascade (Scheme 85).²⁴⁸ Attempts to mediate the sequence using Zn-TMSCl , or using photolysis, led to recovery of the starting material.

Kilburn has employed a SmI_2 -mediated radical/radical sequence involving a methylenecyclopropyl ketone in the preparation of paeonilactone B.^{249,250} Ketyl-olefin addition to the methylenecyclopropane, fragmentation of the resultant radical, and radical–alkyne cyclization gave **89** with good diastereocontrol (Scheme 86). A related radical/radical sequence has been used by Kilburn to access the tricyclic ether skeleton of the eudesmanes (Scheme 86).²⁵¹

Finally, Procter has recently reported lactone radical/radical cyclization cascades using $\text{SmI}_2\text{--H}_2\text{O}$.^{38,64} Reduction of the lactone carbonyl using the activated reagent system triggers the conversion of simple lactones into complex products (Scheme 87).

Scheme 87 Radical/radical cyclization sequences of lactones.

10.1.2 Radical/Anionic Sequences

When planning sequences that require a radical cyclization, care must be taken, as radical intermediates are rapidly reduced by SmI_2 to give organosamariums (Section 3).⁵⁶ Provided that the desired radical cyclization is faster than reduction of the radical to the corresponding anion, radical cyclization–anionic sequences can be realized. For example, efficient 5-*exo*-trig radical cyclization/intermolecular Barbier additions,¹⁹⁷ 5-*exo*-trig radical cyclization/intermolecular Claisen reactions,^{204,247} and 6-*exo*-trig radical cyclization/intermolecular Barbier addition sequences are all possible (Scheme 88).¹⁹⁷

Curran has exploited a SmI_2 -mediated radical/anionic sequence in an approach to the BCD ring system of the penitrem indole alkaloids. Treatment of iodide **90** with SmI_2 and HMPA in the presence of acetone gave **91**, the product of radical cyclization/intermolecular Barbier addition (Scheme 89).²⁵²

Radical cyclization/anionic sequences in which the radical cyclization involves the addition of a ketyl radical anion to an alkene are also possible. For example, carbonyl–alkene cyclization of hept-6-en-2-one and quenching of the resultant organosamarium with electrophiles allows access to an impressive range of cyclopentanol products (Scheme 90).²⁷

Scheme 93 Radical cyclization/intramolecular aldol sequence in an approach to pleuromutilin.

Scheme 94 Anionic/anionic and anionic/radical sequences.

Reissig has reported radical/anionic sequences that involve ketyl radical cyclizations on to indoles.²⁵³ Such a sequence has recently found application in a formal synthesis of strychnine (Scheme 91).²⁵⁴

Enholm has reported radical/anionic sequences involving ketyl radical cyclizations that culminate in intermolecular aldol reactions.²⁵⁵ Procter has recently shown that radical cyclization/intramolecular aldol sequences can also be carried out.²⁵⁶ For example, treatment of dialdehyde **94** with SmI₂ results in a sequential cyclization to

give **95** as a single diastereoisomer (Scheme 92). The diastereoselectivity of the sequence can be ascribed to the chelation of Sm(III) to intermediates. The sequence can be extended further by the addition of SmI₂–H₂O which “switches on” reduction of the lactone formed in the preceding steps (Scheme 92).²⁵⁷

Procter has recently utilized a radical cyclization/intramolecular aldol sequence of the dialdehyde substrate **96** to form the core of the antibacterial natural product pleuromutilin with complete diastereocontrol (Scheme 93).²⁵⁸

10.2 Sequences Initiated by Anionic Reactions

10.2.1 Anionic/Radical and Anionic/Anionic Sequences

Molander recognized the potential of the SmI_2 -mediated Barbier addition to esters for the initiation of sequential processes (Section 8.3). Two types of cascade have been developed that involve nucleophilic acyl substitution: the first type involves double intramolecular Barbier addition to an ester group (anionic/anionic sequences),²⁵⁹ the second type consists of a Barbier addition to an ester followed by a carbonyl–alkene/alkyne cyclization of the resultant ketone (anionic/radical sequences) (Scheme 94).^{193,260} Molander has shown that the double-Barbier anionic/anionic cascades can be used to access a range of fused polycyclic systems.²⁶¹

The sequential nucleophilic substitution–Barbier additions are controlled by the different rates of reduction of the alkyl halides or the tether length if the same halides are present in the substrate.²⁵⁹ Acetals such as **97** have also been used as substrates in anionic/radical cascades: Treatment of **97** with SmI_2 –HMPA gives bicyclic acetal **98** with excellent stereocontrol (Scheme 95).²⁶⁰

Molander has reported a variant of this sequential process that results in alkenyl transfer.²⁶² These anionic/radical sequences can be extended further and Molander has shown that anionic/radical/anionic sequences are possible.¹⁹³ Treatment of **99** with SmI_2 and HMPA in the presence of acetone gave bicyclic alcohol **100** in good yield (Scheme 96).

Molander has also studied the SmI_2 -mediated double-Barbier additions of alkyl dihalides to ketoesters.^{201,202} These anionic/anionic intermolecular/intramolecular sequences use NiI_2 as an additive and irradiation with visible light, and allow access to a range of bicyclic and tricyclic systems. The reactions proceed by reduction of the more reactive alkylhalide, intermolecular Barbier addition to the ketone, lactonization, and a second Barbier addition to the lactone carbonyl (Scheme 97).²⁰¹

Scheme 95 Anionic/radical sequence to form a heterocyclic product.

Scheme 96 Anionic/radical/anionic sequence.

Scheme 97 Intermolecular anionic/intramolecular anionic sequence.

The reagent's reducing power is accompanied by striking selectivity and it is this combination that continues to capture the imagination of synthetic chemists, and new applications are appearing at a significant rate over 30 years after the seminal work of Kagan. However, many challenges remain. For example, a complete understanding of the mechanism of reactions mediated by SmI_2 still eludes us, as does a full picture of the role additives play in modifying the active Sm(II) species present in solution. Furthermore, extension of the reagent's reducing range to new substrate classes, the development of new cascade processes, the discovery of ligand-controlled asymmetric processes, and the development of practical reagent systems that are catalytic in Sm are challenges for the future.

11 CONCLUSION

SmI_2 is set to retain its privileged status amongst reagents for synthesis for many years to come.

The S_{RN}1 Reaction

Javier I. Bardagí, Victoria A. Vaillard and Roberto A. Rossi

INFIQC, Departamento de Química Orgánica, Facultad de Ciencias Químicas, Universidad Nacional de Córdoba, Ciudad Universitaria, Córdoba, Argentina

1 INTRODUCTION

Nucleophilic substitution is feasible through processes that involve electron transfer (ET) steps. In these reactions, a compound bearing a suitable leaving group is substituted at the ipso position by nucleophiles. The S_{RN}1 reaction, which stands for unimolecular radical nucleophilic substitution, is a chain process that involves radicals and radical anions as intermediates.

The S_{RN}1 mechanism was first proposed for the substitution of alkyl halides bearing electron-withdrawing groups (EWGs) in the α position and a suitable leaving group.^{1,2} In 1970, Bunnett applied this mechanism to unactivated aromatic halides.^{3,4} Later on, other substrates such as vinyl halides, perfluoroalkyl halides, alkylmercury chlorides, as well as cycloalkyl, bridgehead, and neopentyl halides were reported to react by this mechanism.

The process has a considerably wide scope. Many substituents, such as alkyl groups, OR, OAr, SAr, CF₃, CO₂R, NH₂, NHCOR, NHBoc, SO₂R, CN, COAr, NR₂, and F are compatible with the reaction. Even though the reaction is not inhibited by the presence of negatively charged substituents such as carboxylate ions, oxyanions, as a general rule, hinder the process. Normally, substituents such as NO₂ groups are not suitable for S_{RN}1 substitution on aromatic substrates, but are important EWGs on aliphatic substrates, favoring the ET process.

In addition to halides, other leaving groups are known, that is, (EtO)₂P(O)O[−], RS[−], ArOS[−], ArO₂S[−], PhSe[−], Ph₂S, RSN₂ (R = *t*-Bu, Ph), BF₄N₂, R₃N, N₂, N₃[−], NO₂[−], and HgX[−]. Thus, ArOH and ArNH₂ are ultimately the leaving groups through phosphate esters and ammonium salts.

Carbanions from hydrocarbons, nitriles, nitroalkanes, ketones, esters, *N,N*-dialkyl acetamides, and *N,N*-dialkyl thioamides, as well as mono- and dianions from β -dicarbonyl compounds are some of the most common nucleophiles through which a new C–C bond can be formed. C–C instead of C–O or C–N bond formation can be achieved by using ArO[−] ions or aromatic nitrogen nucleophiles in reactions with aromatic substrates. However, these nucleophiles afford O- and N-alkylation products in the reaction with alkyl halides bearing an EWG.

The S_{RN}1 mechanism has proved to be an important route to ring-closure reactions, mainly in aromatic systems. The synthesis of indoles, carbazoles, isoquinolones, and other heterocycles, as well as of a large number of natural products, has been achieved by this process.

Nucleophiles derived from Sn, P, As, Sb, S, Se, and Te react through the heteroatom to form a new C-heteroatom bond.

Several reviews have been published in relation to the S_{RN}1 mechanism of substitution at sp³ and sp² carbons,^{5,6} to aromatic photoinitiated substitutions^{7,8} to reactions performed under electrochemical catalysis,^{9,10} and to the synthetic applications of the process.^{11,12}

2 MECHANISM

The $S_{RN}1$ mechanism is presented in Scheme 1. In the initiation step, the radical anion of substrate $RX^{\cdot-}$ can be formed by an ET from the nucleophile or from a suitable electron source; the ET to unsubstituted alkyl halides is proposed to be a dissociative reaction.¹³ $RX^{\cdot-}$ fragments to afford the radical $R^{\cdot}$ and the anion of the leaving group. The radical thus formed can react with the nucleophile to give the radical anion of the substitution product $RNu^{\cdot-}$, which by ET to the substrate forms the intermediates required to continue the propagation cycle.

The mechanism has termination steps that depend on the substrate, the nucleophile, and the experimental conditions. Not many initiation events are needed, but in this case, the propagation cycle must be fast and efficient enough to allow long chains to be built up.

For a given aryl moiety, there is a broad correlation between the reduction potential and its reactivity in $S_{RN}1$ reactions.¹⁴ The order of reduction potential in liquid ammonia, $PhI > PhBr > PhNMe_3I > PhSPh > PhCl > PhF > PhOPh$, coincides with the reactivity order determined under photoinitiation. By competition experiments of pairs of halobenzenes toward $^-CH_2COt-Bu$ ions under photoinitiation, the span in reactivity from PhF to PhI was found to be $\sim 100\,000$.¹⁵

Radical probes (see **Radical Kinetics and Clocks**) have been used to demonstrate the formation of radicals along the propagation cycle and also as a synthetic tool to obtain heterocyclic compounds. Products from ring closure, ring opening, or from rearrangement of the radicals were thus taken as evidence for the

Scheme 1 Representation of the mechanism of the $S_{RN}1$ reaction.

presence of these intermediates. Inhibition by radical traps has been extensively used to provide mechanistic evidence. Those most frequently employed are di-*t*-butylnitroxide, or 2,2,6,6-tetramethylpiperidiny-1-oxy (TEMPO), and radical anion scavengers such as *p*-dinitrobenzene.

Spontaneous or thermal ET is a possible initiation step depending on the relationship between the electron affinity of the substrate and the oxidation potential of the nucleophile. Even though photoinduction is a widely used initiation method, there have not been many mechanistic studies. These photoinduced ET can conceivably be accomplished in one of the following ways: (i) homolytic cleavage of the C–X bond; (ii) ET from the nucleophile to the excited ArX , generating a radical anion that enters the cycle; (iii) ET within an excited charge transfer complex; and (iv) photoejection of an electron from the excited nucleophile. Depending on the nature of RX , the nucleophile, and the experimental conditions, any of these mechanisms could probably be considered as an initiation step.

The process allows the possibility of affording the substitution of an unreactive nucleophile through *entrainment* conditions.¹⁶ Entrainment is useful when the nucleophile is rather unreactive at initiation, but quite reactive at propagation. Under these conditions, the addition of another nucleophile that is more reactive at initiation increases the generation of intermediates and allows the less reactive nucleophile to establish its own propagation.

Quantum yields of photoinitiated reactions have been used as a qualitative measure of the chain length. Quantum yields from 50 to 20 have been determined for the substitution of halonaphthoxide ions and PhI by $(EtO)_2PO^-$ ions.¹⁷ The quantum yields for the substitution of 4-nitrocumyl chloride with N_3^- ions and quinuclidine have been determined to be 6000 and 3.5, respectively.¹⁸ For the reaction of α -4-dinitrocumene with N_3^- ions, the quantum yield was 570.¹⁸

The photoinduced initiation reaction may have, however, a low quantum yield due to a fast backward ET that annihilates the ion pair before cage separation occurs. This will result in a less efficient source of radicals. In the case of nucleophiles reactive at the initiation and propagation pathways, the quantum yields for substitution (Φ_{global}) depend both on the efficiency of initiation and on the turnover in the propagation steps. Thus, the magnitude of the chain length of any $S_{RN}1$ reaction can

easily be derived from the overall quantum yield by knowing the quantum yield of initiation. The latter could be obtained if the propagation cycle is eliminated or markedly reduced in comparison with the initiation step. The chain length can then be obtained from (1):

$$\text{Chain length} = \Phi_{\text{global}} / \Phi_{\text{initiation}} = \Phi_{\text{propagation}} \quad (1)$$

The quantum yield for substitution of neophyl iodide by [−]CH₂COPh ion was determined to be 0.127.¹⁹ The quantum yield of initiation, evaluated by suppressing the propagation steps with the presence of di-*t*-butylnitroxide as radical trap, had a value of 10^{−3}. On the basis of both quantum yields, the chain length or Φ_{propagation} obtained for the reaction was approximately 127. This is the first report of Φ_{propagation}, which is a direct measure of the chain length for an S_{RN}1 process, demonstrating that overall quantum yields lower than unity cannot be taken as a criterion for the absence of a chain reaction.

Another method to initiate the S_{RN}1 reaction is the use of inorganic salts. Although several inorganic salts have been tested, the most commonly used is the ferrous ion. For instance, [−]CH₂CO*t*-Bu, *N*-acetylmorpholine, and a number of higher *N*-acylmorpholine ions react with ArX induced by FeSO₄ to give good substitution yields,²⁰ comparable to the substitutions of PhI with the enolate ions of 2-acetylfurane,²¹ 2-acetylthiophene,²¹ and 2-acetyl-*N*-methylpyrrole.²² The substitution of 1-iodoadamantane (1-AdI), neopentyl iodide, and 7-iodobicyclo[4.1.0]heptanes with carbanions from ketones²³ and of 1-AdI with the anion from thioacetylmorpholine²⁴ have been successfully achieved in the presence of FeBr₂ in dimethylsulfoxide (DMSO).

Electrons from alkali metal dissolved in liquid ammonia or Na(Hg) or from a cathode have also been used to initiate S_{RN}1 reactions. The solvated-electron initiation can be of importance whenever the products coming from a benzyne mechanism are to be avoided.^{4,25}

Electrochemical initiation is an approach that has been successfully applied in numerous cases with aromatic and heteroaromatic substrates.^{9,10} When the radical anion of the substrate fragments fast, reduction is the main reaction pathway; however, high yields of S_{RN}1 products can be obtained using redox catalysis. Electrochemical methods have been

used to determine the absolute rate constant of aromatic radicals with nucleophiles. A large number of these values are close to the diffusion limit.

The dissociation of the aromatic radical anion intermediates occurs through an intramolecular ET from the π system to the σ C–halogen bond. Both, theoretical and experimental evidences show the formation of π radical anions in the ET to ArX. In this family, the π and σ systems are adjacent and orthogonal. The main reaction coordinates for the intramolecular ET from the π to the σ state, which dissociates into aryl radicals and X[−] ions, are the C–X bond elongation and bending with respect to the aryl plane.^{26,27}

Relative reactivities for pairs of nucleophiles toward the same radical can be obtained from the ratio of the two substitution products in competition reactions. The span in reactivity is larger for aromatic ketones than for aliphatic ketones, with the following reactivity order: [−]CH₂COMe (1.00), [−]CH₂COPh (7.5), and anthrone anion (16.5).²⁸ In addition, the reactivity order of enolate anions of other aromatic ketones versus [−]CH₂COPh anion was determined to be as follows: carbanions from 2-acetylthiophene (0.49),²¹ 3-acetyl-*N*-methylpyrrole (0.73),²² 2-acetylfurane (0.83),²¹ 2-naphthyl methyl ketone (1.1), and 2-acetyl-*N*-methylpyrrole (2.6).²²

As opposed to the case of aryl radicals, limited information is available on the relative reactivities of nucleophiles toward aliphatic radicals. By competition experiments, it was found that 1-adamantyl radicals are more selective than phenyl radicals toward carbanions. The following relative reactivity order has been determined for the reaction of 1-adamantyl radical with the carbanions: anthrone (80)²⁹ > CH₃NO₂ (32)²⁹ > CH₃COPh (11)²⁹ > *N*-acetylthiomorpholine (3.3)²⁴ > CH₃COCH₃ (1.0).²⁹

One of the main goals of the S_{RN}1 mechanism lies in the possibility of obtaining disubstituted compounds when the reaction is performed with substrates bearing two leaving groups. This type of compounds may react to form monosubstitution and/or disubstitution products, depending on the leaving groups, their relative positions in the molecule, the nucleophile, and the solvent. For aliphatic substrates, reactivity also depends on the flexibility of the bridge. Few examples of trisubstitutions³⁰ or four consecutive S_{RN}1 substitutions are known.^{31–33}

3 S_{RN}1 REACTIONS WITH AROMATIC SUBSTRATES

3.1 Carbanions as Nucleophiles

The reaction with carbanions to afford a new C–C bond constitutes one of the more representative examples of S_{RN}1 reactions with aromatic substrates. Carbanions derived from hydrocarbons, such as 1,3-pentadienyl, 1-(4-anisyl)propenyl, fluorenyl, and indenyl anions, have been studied along this line. The regiochemistry of the coupling favors the formation of the more stable radical anion intermediate.⁵

On the other hand, the enolate ions of aliphatic ketones are the carbanions most widely studied. The solvents and the reaction conditions of choice usually involve liquid ammonia or DMSO and irradiation. However, for some systems spontaneous initiation is also possible. For example, PhI reacts with [−]CH₂COR ions in DMSO in the dark; halo-heteroaromatic compounds are also substrates able to react in the dark in liquid ammonia.

The enolate ions of acetone, pinacolone, 3-pentanone, 4-heptanone, and 2,4-dimethyl-3-pentanone react through the S_{RN}1 mechanism to afford α-arylation products under photostimulation.⁵

In the reaction of the [−]CH₂COME ion with 2-chloroquinoline, the effect of solvent was studied, with the same reaction time and under photostimulation, from liquid ammonia (90%) to tetrahydrofuran (THF) (82%), DMF (74%), dimethoxyethane (28%), diethyl ether (9%), or benzene (4%).³⁴

In unsymmetrical dialkyl ketones, isomeric enolate ions can be formed. The equilibrium concentration of two possible enolate ions and the selectivity of the attacking radical largely determine the distribution of two possible arylated products. A case in point is the reaction of the anion from 2-butanone where phenylation occurs preferentially at the more substituted α-carbon, whereas,³⁵ with the anion from *i*-propylmethylketone **1**, 1-phenyl derivatives **2** predominate^{36,37}; when the same anion reacts with 2-chloroquinoline, the tertiary (**3**) to primary substitution ratio is approximately 4.8 (**2**).³⁸ Substituents located ortho to the leaving group of the substrate generally favors the attack at

the primary α-carbon of the anion.⁵

Products derived from α-arylation of cyclobutanone, cyclopentanone, cyclohexanone, cycloheptanone, cyclooctanone, and 2-indanone are obtained in good yields (58–95%) under irradiation in liquid ammonia.³⁹

The [−]CH₂COPh ion can be arylated in liquid ammonia by initiation with K metal or Na(Hg), or under photostimulation. In the coupling step, this anion demonstrated to be more reactive than [−]CH₂COME ion, yet the latter proved to be more reactive in the initiation step.²⁸

The anions from other aromatic ketones, such as methyl 2-naphthylketone, 2-acetyl furan, 2- and 3-acetylthiophene, 2- and 3-acetyl-*N*-methylpyrrole, anthrone, and tetralone, can also be arylated.⁸ Some examples are shown in (**3**).

When aromatic substrates with two leaving groups such as **4** (Scheme 2) react with enolate ions from ketones, mono and disubstitution products can be obtained, depending on the nature of the leaving group and their relative position in the molecule and on the nucleophile. Upon receiving an electron, substrate **4** forms the radical anion **4**^{•−}, which fragments at the more labile C–X bond to give radical **5**. Then, this radical intermediate **5** reacts with the nucleophile to form the radical anion **6**. This radical anion can transfer the extra electron to another molecule of **4** (ET_{inter}) to furnish product **7**, or to the second C–Y bond by an intramolecular ET (ET_{intra}). If ET_{intra} occurs, **6** fragments to afford radical **8**, which by coupling with the nucleophile followed by an ET reaction, generates the disubstitution product **9** (Scheme 2). This behavior is observed with dihalo substrates, not only with anions derived from ketones but with other nucleophiles as well.⁵

Scheme 2 Two possible pathways in S_{RN}1 reactions of a substrate with two leaving groups.

For instance, in the reaction of *o*-C₆H₄Br₂ with the [−]CH₂CO*t*-Bu ion, only disubstitution is observed,⁴⁰ while *o*-iodohalobenzene (X = Cl, Br, or I) reacts with several enolate ions from aromatic ketones to give the monosubstitution products with the retention of one halogen.⁴¹ The extent of dehalogenation is discussed in terms of the energies of the intramolecular ET from the π* molecular orbital (MO) of the ArCO to the σ* MO of the C–X bond in radical anions **6**, proposed as intermediates.

Other cases where disubstitution is achieved is in the reaction of 2,5- and 2,6-dibromopyridines, 2,3-, 2,6-, and 3,5-dichloropyridines, and 5,7-dibromo-8-methoxyquinoline with the [−]CH₂CO*t*-Bu ion^{42,43}; monosubstitution occurs from the selective displacement of chlorine from C4 of 4,7-dichloroquinoline when the same anion is used.⁴³

Carbanions derived from esters, carboxylate salts, *N,N*-disubstituted amides, thioamides, imides, and β-dicarboxylic compounds are used as nucleophiles to form new C–C bonds in S_{RN}1 reactions with aromatic substrates. α-Arylacetic esters are obtained by the reaction of ArX with the [−]CH₂CO₂*t*-Bu ion, under photo or Fe initiation. Lower yields of substitution are achieved with the anions of tertiary esters bearing β hydrogens. Other carbanions arylated under photostimulation includes the anions from ethyl phenylacetate, methyl diphenylacetate,

and *t*-butyl-3-butenate. For the last one, arylation occurs at the terminal site of the π system.⁵

On other hand, it is possible to obtain *N,N*-disubstituted-α-arylacetamides by the reaction of ArX with carbanions from *N,N*-disubstituted amides. Unsymmetrical α,α-diarylated amides can also be prepared by the reaction of the anions of the monoarylated products with ArX (**4**).^{25,44}

Ar = 1-Naphthyl, 9-phenanthryl or 9-anthracenyl. Ar¹ = Ph

Ar = Ph. Ar¹ = 9-Phenanthryl or 9-anthracenyl (4)

Stereoselective coupling of an aromatic radical with a nucleophile is found in the reaction of 1-iodonaphthalene with an imide ion containing a chiral auxiliary, where the diastereomeric isomers of the substitution compound are formed, depending on the metal counterion used. For example, the highest stereoselectivity is found with Li⁺ as a counterion at low temperature, and with Ti(IV).⁴⁵

1,3-Dianions from β-dicarbonylic compounds react quite well under irradiation through the terminal carbon site. Monoanions from β-dicarbonyl or β-cyanocarbonyl compounds react under electrochemical initiation with *p*-C₆H₅COC₆H₄Br and *p*-NCC₆H₄Cl, and in lower yields with

Scheme 3 Competition between ET and fragmentation of $[\text{ArCH}_2\text{CN}]^-$ radical anion.

2-chloroquinoline. An application of this reaction to obtain the natural product nebularine analog comprises the substitution of 2-methylsulfonylnebularine by ${}^-\text{CH}(\text{CO}_2\text{Et})_2$ ions.⁴⁶

The photoinitiated reactions of 2-bromobenzonitrile and 2-bromo-3-cyano-pyridine with the ethyl cyanoacetate ion afford the substitution product in good yields by an $\text{S}_{\text{RN}}1$ process.

In the coupling reaction of phenyl radical with the ${}^-\text{CH}_2\text{CN}$ ion, the radical anion fragments into benzyl radical and CN^- ions ($\text{Ar} = \text{Ph}$, Scheme 3 lower case), where toluene is the principal product observed.^{47,48}

However, with 1-chloronaphthalene, polycyclic aromatic halides, substituted haloarenes with a $-\text{COPh}$ group, or halopyridines, substitution products ArCH_2CN are formed in good yields (upper case in Scheme 3). With these substrates, the extra electron of the radical anion resides in the aryl group and C–CN fragmentation is avoided. Other nitrile ions that can be used in this type of reaction include anions from phenylacetonitrile, 2-phenylbutyronitrile, and 2-cyclohexylidene-acetonitrile. For the last one, the substitution products are obtained at C γ position.⁴⁹

Nitronate ions can be used in $\text{S}_{\text{RN}}1$ reactions as nucleophiles, but only products of fragmentation of the radical anion of the substitution products are obtained.⁵⁰

One of the less reactive nucleophiles in $\text{S}_{\text{RN}}1$ is the CN^- ion.⁵ However, the substitution of $p\text{-C}_6\text{H}_5\text{COC}_6\text{H}_4\text{Br}$ is achieved under electrolysis, and the photoinitiated substitution of 2-methylsulfonylnebularine and 1-halo-2-naphthoxide ions has been reported. The diazosulfides ArN_2SPh are the best substrates to be substituted by the CN^- ion in DMSO, under irradiation or electrode stimulation. The system is favored by the positive reduction potential of the substrate with respect to the substitution products, which in turn helps the $\text{S}_{\text{RN}}1$ propagation cycle. When the aryl group is also substituted by Br or Cl, the introduction of two CN groups is achieved with good yields.⁵¹

Interesting examples in the aromatic family involve ArO^- ions, which react with ArX to give C–C instead of C–O bond formation. The reaction of PhO^- ions induced electrochemically with 4-bromobenzophenone or 4-chlorobenzonitrile, affords ortho (40%) and para (20%) coupling products (5).⁵²

(5)

The 1- and 2-naphthoxide ions react under irradiation with different ArX . For 1-naphthoxide ions, a mixture of 2- and 4-aryl, together with 2,4-diaryl-1-naphthol products, is formed. Only substitution at C₄ occurs with the 2-methyl-substituted anion, while in the reaction with 4-methoxy-1-naphthoxide ion substitution takes place at C₂, accompanied by addition at C₄.⁵³

2-Naphthoxide ions react with ArX to give substitution only at C₁ of the naphthalene ring⁵⁴; 2,4 or 2,6-di-*tert*-butyl, $p\text{-MeC}_6\text{H}_4\text{O}^-$, and $p\text{-F}_3\text{COC}_6\text{H}_4\text{O}^-$ ions react under irradiation with $p\text{-FC}_6\text{H}_4\text{Br}$, $p\text{-CF}_3\text{C}_6\text{H}_4\text{Br}$, and $p\text{-F}_3\text{COC}_6\text{H}_4\text{Br}$ to give fluorinated biaryl derivatives.⁵⁵

The reaction of the 9-phenanthrenolate ion under photostimulation in DMSO with PhI affords the arylation product at C₁₀ position. In the reaction of this ion with *o*-diiodobenzene, substitution is obtained not only at C₁₀ but also at oxygen to give benzo[*d*]phenanthro[9,10-*b*]furan derivative.⁵⁶ This is a very rare example in which an aryl radical couples at oxygen.⁵⁷

3.2 Tin Nucleophiles

ArCl reacts in a photostimulated reaction with an R_3Sn^- ion by the $\text{S}_{\text{RN}}1$ mechanism, but ArBr and

Scheme 4 Synthesis of polyarylated products by S_{RN}1–Stille tandem reactions.

ArI react by the halogen metal exchange (HME) pathway.⁵⁸

R₃Sn[−] ions from trimethyltin chloride and triphenyltin chloride can be prepared with Na metal in liquid ammonia. Competition experiments demonstrated that Me₃Sn[−] and Ph₃Sn[−] anions have the same reactivity in the propagation step, but the former is more reactive in the initiation step.⁵⁸

Disubstitution products are formed in high yields for the reaction of *o*-, *m*-, and *p*-C₆H₄Cl₂ under photostimulation. The trisubstitution product can be obtained from 1,3,5-trichlorobenzene.³⁰ Disubstitution products from pyridines also are acquired from dichloropyridines.³⁰

ArOH are readily converted into ArOP(O)(OEt)₂, which on reaction with Me₃Sn[−] and Ph₃Sn[−] ions afford ArSnMe₃ and ArSnPh₃ in good yields. This methodology is used for the synthesis of mono, di, and tristannylated products.^{59,60} On the other hand, ArNH₂ can be converted into ArNMe₃⁺ salts, which react with Me₃Sn[−] ions to give ArSnMe₃ in good yields.^{61,62}

This synthetic strategy has been employed to obtain a variety of stannanes, which have then been used in cross-coupling reactions to afford arylation products (Scheme 4). Thus, this sequence can be successfully applied to build large molecules.^{62,63}

Recently, a similar approach to the synthesis of 6-substituted uracils **11** from 6-chloro-2,4-dimethoxypyrimidine **10** (6) was reported. By performing a three-step, one-pot reaction S_{RN}1–Stille–hydrolysis, it was possible to obtain 6-aryl- and 6-acyl-substituted uracils in good yields.⁶⁴

Other tin nucleophiles can be prepared by a Sn–alkyl bond fragmentation of a R₄Sn compound. When *p*-anisyltrimethyltin reacts with Na metal in liquid ammonia, the Sn–Me bond is cleaved to give the corresponding nucleophile. This reacts with *p*-chlorotoluene to afford the corresponding substitution product in high yields.⁶⁵

The dianion Me₂Sn^{2−} can be formed by the reaction of Me₂SnX₂ (X = Cl, Br) with Na metal, and affords Ar₂SnMe₂ in the photostimulated reaction with ArCl. A synthetic application of these stannanes involves the homocoupling of the aryl groups mediated by Cu.⁶⁶

The leaving group ability of the Me₃Sn group in electrophilic substitutions allows the synthesis of asymmetric diaryl ketones in good yields (40–78%) through the reaction of Me₃SnAr, synthesized by S_{RN}1 reactions, with ArCOCl. These reactions are completely regioselective, allowing the synthesis of diarylketones not usually available under Friedel–Crafts reactions. The reaction of stannane **12** with PhCOCl in PhCl as solvent, for instance, furnished diarylketone **13** in 78% yield (7).⁶⁷ Specific di- and triketones are obtained in good to excellent yields (45–83%).⁶⁸

3.3 Nucleophiles Derived from N, P, As, and Sb

The first example of an S_{RN}1 type process was the reaction of ArX with the NH₂[−] ion.³ Thus, ArNH₂

products can be obtained by reaction with 1-chloro-2,4,5-trimethylbenzene and 1-chloro-2,3,5-trimethylbenzene, *o*-MeOC₆H₄X (X = Br or I), 2-iodo-1,3-dimethylbenzene, PhOPh, 3-bromothiophene, and ArOP(O)(OEt)₂, under K metal stimulation in liquid ammonia.⁴ NH₂[−] ions react under photoinitiation with 2-bromo-1,3,5-trimethylbenzene with good substitution yields (70%).⁶⁹

PhNH[−] ions reacts under K metal stimulation with PhI, and substitution occurs not only at nitrogen but also at the ortho and para carbons of the phenyl ring.⁴ On the other hand, the 2-naphthylamide ion reacts under photoinitiation with PhI, *p*-MeOC₆H₄I, and 1-iodonaphthalene in liquid ammonia to give 1-aryl-2-naphthylamines in good yields (8%).⁷⁰

Arylpyrroles, arylindoles, and arylimidazoles are synthesized electrochemically by the reaction of pyrrolyl, indolyl, and imidazolyl ions in liquid ammonia. For the pyrrolyl ion, substitution at C₂ on the heterocycle is the main product⁷¹; however, substitution at C₃ is obtained when C₂ and C₅ bear substituents.⁷²

For indolyl ions, substitution at C₃ is the major reaction observed.⁷² In the case of 4-methylimidazolyl ion, the yield of substitution product indicates that the C₅ position is more reactive than the C₂ position. For the 2-methylimidazole anion, the reaction becomes regioselective and only substitution at C₄ is obtained.⁷² This is also observed for the anions derived from 2-(*p*-anisyl)imidazole and 2-methyl-5-nitroimidazole in the reaction with ArI.⁷³

Electrochemical induction of different ArX bearing EWGs, in the presence of uracil ions in DMSO allows the synthesis of the corresponding 5-aryluracils.⁷³

The (EtO)₂PO[−] ion reacts with ArX to yield ArP(O)(OEt)₂ under irradiation either in liquid ammonia, MeCN/THF, DMF, or DMSO. The same anion also reacts under Fe²⁺ induction with ArI in liquid ammonia. Arylbromides ortho-functionalized by NH₂, OMe, or CONH₂ react under these

conditions to ArP(O)(OEt)₂ with low to excellent yields.⁵

When the (EtO)₂PO[−] ion reacts with haloiodobenzenes in liquid ammonia, the following behavior is observed: monosubstitution at iodine is obtained with *o*-, *m*-, and *p*-fluoro compounds; disubstitution is achieved with *o*- and *p*-chloroiodobenzenes; whereas meta isomers only afford substitution of iodine. With *o*-, *m*-, and *p*-dibromo and diiodobenzenes reaction with the (EtO)₂PO[−] ion gives mainly disubstitution products.⁷⁴

Other P-nucleophiles such as Ph₂P[−] ions react with different ArX to afford substitution products in good yields. The ions Ph(OBu)PO[−], Ph₂PO[−], (EtO)₂PS[−], (Me₂N)PO[−], and (C₆H₅CH₂)₂PO[−] react with PhI in liquid ammonia under photostimulation in nearly quantitative yields.⁵

When Ph₂As[−] ions react under irradiation with *p*-halotoluenes, *p*-haloanisoles, 1-bromonaphthalenes, and 9-bromophenanthrene, arsines with scrambled aryl ring are formed. The S_{RN}1 mechanism, involving the formation of arsine radical anion intermediates, adequately accounts the products observed. For the radical anion intermediates formed, two possible reactions can occur: ET or C–As bond-breaking (Scheme 5).⁷⁵

When the substrate has a low-energy lowest unoccupied molecular orbital (LUMO), such as 4-chlorobenzophenone,⁷⁵ 2-chloroquinoline,⁷⁵ and 6-chloro-2,4-dimethoxypyrimidine,⁷⁶ the radical anion intermediates formed do not fragment, and the straightforward substitution products are obtained in 100%, 76%, and 70% yields, respectively.

3.4 Nucleophiles Derived from S, Se, and Te

Sulfur-centered anions have been used in S_{RN}1 reactions and the results observed depend not only on substrates but also on the nucleophile applied. For alkanethiolate ions, depending on the nature of ArX and RS[−] involved, the fragmentation reactions may compete with the substitution process. Nevertheless, efficient substitution is obtained with compounds bearing EWGs as well as polycyclic or heterocyclic halides.⁵

The HO(CH₂)₂S[−] ion is used to obtain benzo[*e*]thiazine by an S_{RN}1 reaction with 1-bromo-2-aminonaphthalene followed by cyclization reaction

Scheme 5 Representation of the scrambling mechanism of aromatic moieties in the reaction of ArX with Ph₂As[−] ions.

after replacement of OH by Cl (9).⁷⁷

The same procedure has been applied to afford thiazines and benzo[*g*]thiazines by reaction of this anion with substituted *o*-bromoanilines, 2-amino-3-halo- or 3-amino-2-halopyridines, and with 1-amino-2-bromonaphthalene.⁵ By a double-S_{RN}1 reaction of 1- or 2-halonaphthalenes with [−]S(CH₂)_{*n*}S[−] dianions, the corresponding bis-sulfides are obtained.⁷⁸

Ar¹S[−] ions react with ArI in liquid ammonia under irradiation to form ArSAr¹ in good yields. ArBr reacts with PhS[−] ions under thermal, photochemical, or electrochemical initiation in DMF, MeCN, or DMSO. ArN₂BF₄ reacts with Ar¹S[−] to give ArSAr¹ via initial formation of the corresponding ArN₂SAr¹.⁵

Dihalobenzenes and ArN₂⁺ salts bearing a halogen substituent give mainly disubstitution in the reaction with PhS[−] ions. The synthesis of phenyl, naphthyl, and pyridyl derivatives bearing two ArS moieties or even two different ArS groups can be achieved by successive S_{RN}1 reactions.⁵

On the other hand, when 2-pyrimidinethiolate ions are allowed to react with *o*-, *m*-, and *p*-C₆H₄Cl₂, monosubstitution is the principal reaction observed, which can be explained on the basis of Scheme 2 (ET_(inter) > ET_(intra)).⁷⁹

RCOS[−] ions represent another type of nucleophiles centered on sulfur which react in S_{RN}1 type processes. It is known that ArN₂BF₄ reacts with MeCOS[−] or PhCOS[−] ions to give arylthioesters, which can be either isolated or react further providing a convenient one-pot process to access other aromatic sulfur derivatives (10).⁸⁰

Aryl methyl and symmetrical diarylsulfides were prepared by photoinduced reactions of MeCOS[−] ions with ArX (X = Br or I) in moderate to good yields. For these reactions, *entrainment* conditions with *t*-BuOK are required. The yields of diarylsulfides increase when appropriate reactions conditions are chosen. For example, when 1-bromonaphthalene and the MeCOS[−] ion (0.125 M, ratio 1 : 1) react, 42% diarylsulfide is obtained. On the other hand, if the concentration of the nucleophile is increased to 0.25 M and the ratio substrate/nucleophile is 1 : 0.6, the yield of diarylsulfide is 83%.⁸¹

In addition, MeCOS[−] and NH₂(NH)CS[−] ions were used as nucleophiles in S_{RN}1 reactions with *p*-NCC₆H₄Cl and 2-, 3-, and 4-chloropyridines under electrochemical conditions to afford ArS[−], ArSAr, and ArSSAr (Scheme 6).⁵

A study on the reactivity of NH₂(NH)CS[−], MeCOS[−], and PhCOS[−] ions toward 1-naphthyl

Scheme 6 Generation ArS^- ions from reaction of $\text{Ar}^\bullet$ and $\text{NH}_2(\text{NH})\text{CS}^-$.

radicals determined by competition experiments indicates that all anions show similar rate constants for the coupling reaction (1×10^9 , 1.2×10^9 , and $3.5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ respectively).⁸²

Although PhCOS^- is the most reactive anion in the coupling step, the overall reaction is the least efficient as compared to $\text{NH}_2(\text{NH})\text{CS}^-$ and MeCOS^- ions. A quantum yield higher than unity evidences a chain mechanism for $\text{NH}_2(\text{NH})\text{CS}^-$ and MeCOS^- ions. PhCOS^- adds to the 1-naphthyl radical, but is neither able to initiate the reaction nor to keep the propagation cycle.⁸²

The Na_2Se nucleophile can be formed by the reaction of Se and Na metals in liquid ammonia and reacts under irradiation with PhI to give $(\text{PhSe})_2$ (78%), after oxidation of the PhSe^- ions formed.⁸³ Z_2^{2-} ($\text{Z} = \text{Se}$ or Te) is also formed by electrogeneration from metals using sacrificial electrodes in MeCN. After that, the ions react with ArX to achieve ArZZAr .⁵ Finally, PhSe^- and PhTe^- substitute various ArX under irradiation; straightforward and scrambled products are obtained depending on both the nucleophile and the ArX employed.⁸⁴

3.5 Ring-Closure Reactions

3.5.1 $\text{S}_{\text{RN}}1$ Reaction Followed by a Polar Reaction

One of the most widely studied approaches to ring-closure reactions is the $\text{S}_{\text{RN}}1$ substitution of aromatic compounds that have an appropriate ortho substituent Z to the leaving group, such as **14**, which can react with a nucleophile to afford product **15**. The ring-closure product **16** is obtained by the spontaneous reaction between the Nu and Z groups (11).

(11)

A significant example is the synthesis of indoles by the photostimulated reaction of *o*-iodoaniline **17** with $^- \text{CH}_2\text{COR}$ ions in liquid ammonia to give product **18**, which spontaneously cyclizes to the substituted indole **19** (12).⁸⁵ The analogous reaction of *vic*-aminohalo pyridines leads to azaindoles (70–95%).⁸⁶

(12)

Photostimulated reactions of **17** with $^- \text{CH}_2\text{COAr}$ ions in DMSO afford 2-substituted indoles such as **19** [$\text{R} = \text{Ph}$ (88%), 1-Naph (73%), 2-Pyr (64%), and 3-Pyr (74%)], with heteroaromatic ketones, such as 2-acetylthiophene and *N*-methyl-2-acetyl-pyrrole, afford **19** with 82% and 93% yields, respectively.⁸⁷ Photostimulated reactions of **17** with enolate anions derived from cyclic ketones, such as **20**, afford the fused indoles **21** in moderate to high yields (13).⁸⁸

Benzo[*e*]- and benzo[*g*]indoles can be obtained through the reaction of 1-bromo-2-amino or 1-amino-2-bromonaphthalene, respectively, with the [−]CH₂CO*t*-Bu ion.⁷⁷

The synthesis of 3-substituted isoquinolin-1(2*H*)-ones can be achieved by photoinduced S_{RN}1 reactions in DMSO by reacting *o*-iodobenzamide with enolate ions of aromatic and aliphatic ketones in 68–87% yields. With cyclic ketones, these reactions afford fused isoquinolinones with moderate to good yields (14).⁸⁹

2-Iodobenzenesulfonamide **23** undergoes photo-stimulated S_{RN}1 reactions in liquid ammonia with ketone enolate ions, yielding 2*H*-1,2-benzothiazine-1,1-dioxides with fair to good yields (67–90%). With cyclopentanone-, cyclohexanone-, and cyclooctanone-derived enolates, fused benzo-thiazine-1,1-dioxides **24** were obtained (15).⁹⁰

The S_{RN}1 approach can be a route to isoquinoline rings and derivatives by reaction of *o*-iodobenzylamines with [−]CH₂COR ions under irradiation. The substitution product **25** spontaneously reacts further by ring closure to give product **26**. If **26** is treated with NaBH₄, tetrahydroisoquinolines **27** are obtained. On the other hand, treatment with Pd/C provides isoquinoline derivatives **28** (Scheme 7).⁹¹

Thienopyridine rings such as **30** can be obtained by the reaction of EtO₂CCH₂S[−] ions with 2-bromo-3-cyanopyridine **29** (and 3-bromo-4-

Scheme 7 Synthesis of tetrahydroisoquinolines (**27**) and isoquinolines (**28**) from *o*-iodobenzylamines and [−]CH₂COR anions by S_{RN}1-ring-closure sequence.

Scheme 8 Synthesis of thienopyridines **30** through the $S_{RN}1$ -nucleophilic addition-hydrolysis sequence.

cyanopyridine), in which the substitution product is deprotonated to afford ultimately **30** in 90% and 98% yields, respectively (Scheme 8).⁹²

An important approach to five- and six-membered ring benzolactams and benzolactones is the carbonylation under phase transfer catalysis (PTC) conditions of ArX bearing NH_2 or OH groups on a side chain ortho to the halogen atom (**16**). Although no mechanistic studies have yet been conducted, the authors suggest that reactions occur via an $S_{RN}1$ mechanism.⁹³

3.5.2 5-*exo* and 6-*exo* Radical Cyclization Followed by an $S_{RN}1$ Reaction

When an aromatic substrate has both a leaving group and a double bond at an appropriate distance as in **31** ($n = 1$ or 2), the radical **32** formed after the

ET and fragmentation can cyclized in a 5-*exo* or 6-*exo* fashion (see **Radical Kinetics and Clocks**), to generate the alkyl radical **33** which is able to react with nucleophiles by the $S_{RN}1$ mechanism to afford the ring-closure substitution product **34** (Scheme 9).

Using this approach, 3-substituted-2,3-dihydro-1-*H*-indoles, 3-substituted-2,3-dihydro-1-*H*-benzo[*e*]indoles (**35**, $Z = N-R$), 2,3-dihydrobenzofurans, and 2,3-dihydrobenzofurans (**35**, $Z = O$) are easily prepared via a 5-*exo* ring-closure process during the propagation cycle in the $S_{RN}1$ reaction (17).⁹⁴

(17)

With $^-CH_2NO_2$ ion as a nucleophile, the sequence provides the corresponding *N*-allyl-3-(2-nitro-ethyl)-2,3-dihydro-1-*H*-indole in 60% yield after a photostimulated reaction ($X = Br$), in the presence of the $^-CH_2COMe$ ion as an entrainment reagent.

Tandem 6-*exo-trig* cyclization- $S_{RN}1$ reactions with 1-(but-3-enyloxy)-2-halobenzenes and 1-(but-3-enyloxy)-2-halonaphthalenes afford 4-substituted chromanes and benzo[*f*]chromanes **36** in good to excellent yields, along with the direct substitution product **37** (18).⁹⁵

(18)

3.5.3 Intramolecular $S_{RN}1$ Reactions

When a substrate bears both the leaving group and also the nucleophilic center, the intramolecular $S_{RN}1$

Scheme 9 5- or 6-*exo* radical ring closure preceding the S_{RN}1 mechanism.

Scheme 10 Ring-closure reaction by an intramolecular S_{RN}1 reaction.

reaction directly leads to the ring-closure product (Scheme 10).

Substrate **38** receives an electron by ET and forms the dianion radical **39**, which by fragmentation of the C–X bond gives distonic radical anion **40**. This is a high-energy intermediate; the ring-closure product provides the more stable conjugated radical anion **41**. Finally, ET furnishes product **42**.

This strategy has been widely used to obtain heterocyclic compounds. For instance, oxindoles **44** were prepared by intramolecular cyclization of the anion of *N*-alkyl-*N*-acyl-*o*-haloanilines **43** (19).⁹⁶

In a similar approach, 3-alkylideneoxindoles were obtained starting from *N*-methyl- α,β -unsaturated

anilides (63–100%) and 1,4-dihydro-2*H*-isoquinolin-3-ones by photocyclization of *N*-acyl-*N*-methyl-*o*-chlorobenzylamines (54–62%).⁵ 1-Phenyl-indanones, tetralin derivatives, and alkaloid structures were synthesized by the same strategy. For instance, alkaloids such as eupoulauramine, tortuosamine, and Ergot-type ones were obtained by intramolecular S_{RN}1 reactions as a key step.⁵

Cephalotaxinone **46**, a natural alkaloid, is the major product in the photoinduced reaction of iodoketone **45** (20).⁹⁷

Scheme 11 Intramolecular reactions of 2-bromophenylalkyl-2-oxazolines. The products depend on the length of the alkyl chain spacers.

The length effect of alkyl chain spacers was studied using 2-halophenylalkyl-2-oxazolines (Scheme 11). When the spacer is $n = 1$ or 2, products from cyclization by $S_{RN}1$ reaction are obtained; for $n = 3$ or 4, the major product is a benzocycloalkane derivative in which the oxazoline has undergone an arenotropic migration from the end of the spacer to the benzo ring, whereas with $n = 0$, the 9-oxalinophenanthrene derivative is the main product observed.⁹⁸

In a similar approach, a tetracyclic isoquinoline derivative was synthesized using 3-[4-(2-bromophenyl)-2-phenylbutyryl]-4,4-dimethyloxazolidin-2-one as substrate. For this reaction, two mechanisms involving an $S_{RN}1$ -type process were proposed.⁹⁹

Benzothiazoles **48** can be obtained in excellent yields (100%) by reaction of **47** ($R = \text{Me}, \text{Ph}$) and acetone enolate ions as entrainment reagent (21).¹⁰⁰

(21)

Photostimulated intramolecular ortho-arylation reactions of bromoarenes linked with pendant

phenoxy containing *N*-substituted tetrahydroisoquinolines such as **49** afford aporphine alkaloid derivatives **50** in good yields (22). This strategy was later extended to the synthesis of a homoaporphine alkaloid **50c** ($n = 2$) from **49c** in 40% yield.¹⁰¹

(22)

Following a similar approach and using the intramolecular arylation of iodobenzyl amide ions **51** with a pendant aryl moiety, the reaction affords phenanthridines **53** derivatives in very good yields.¹⁰² These reactions have been carried out under irradiation in liquid ammonia or DMSO. Dihydrophenanthridines **52** were the straight ring-closure products, which spontaneously oxidize during work-up to give **53** (23).

The synthesis of a series of substituted 9*H*-carbazoles by the photostimulated S_{RN}1 reaction of diarylamines as starting substrate was achieved via an intramolecular C–C bond formation. Anions **54** formed in liquid ammonia or DMSO reacted under irradiation in good yields to 9*H*-carbazoles **55** (R = H, 1-Ph, 1-pyrrolyl, 3-OMe, 3-*t*-Bu) (24).¹⁰³

4 S_{RN}1 REACTIONS WITH VINYLIC SUBSTRATES

Different mechanisms are possible for the nucleophilic substitutions of vinyl halides.¹⁰⁴ For a vinylic S_{RN}1 process, the substrate should not contain vinylic or allylic hydrogens so as to avoid the alternatives of α–β and α–β' elimination–addition reactions, respectively. On the other hand, the presence of a conjugated group such as aryl or 1,3-butadienyl is required to stabilize the intermediate radical anion of the substitution product. Nucleophilic addition to a rearranged radical from a 1,3-hydrogen shift is possible when the vinyl halides have γ-hydrogen atoms.¹⁰⁵

Triphenylvinyl bromide **56** reacts with the [–]CH₂CO*t*-Bu ion to yield the corresponding

Scheme 12 Mechanism of the reaction of vinyl substrate **56** with the [–]CH₂NO₂ ion. Fragmentation of the intermediate radical anion **58** gives the final product **60**.

substitution product in 93% yield by an S_{RN}1 reaction. The anion [–]CH₂COPh does not react under irradiation; however, under *entrainment* conditions ([–]CH₂COMe anion as initiator), it affords 90% of the substitution product.¹⁰⁶

Under similar reaction conditions, [–]CH₂NO₂ ion as nucleophile yields 1,1,2-triphenylpropene **60** by the S_{RN}1 mechanism (Scheme 12).¹⁰⁶ When **56** accepts an electron, it fragments to afford the vinyl radical **57**. This radical then couples with the nucleophile to yield the radical anion **58** that fragments to afford the NO₂[–] ion and the allylic radical **59**, which is finally reduced to the product **60**.

A study was undertaken on the coupling of vinyl radicals with (EtO)₂PO[–], [–]CH₂COR-Bu, and PhS[–] ions, and the competing H-atom abstraction reactions from MeCN or DMSO. The rate constant for H abstraction in DMSO was, for radical **57**, 1.1 × 10⁵ M^{–1} s^{–1}, and that for the coupling of **57** with the PhS[–] ion was calculated to be 1.9 × 10⁷ M^{–1} s^{–1}.¹⁰⁷

The reaction of (*Z*)-1-chloro-1,2-diphenylethene (**61a**) with the Me₃Sn[–] ion afforded the substitution product **62a** by the S_{RN}1 mechanism. Similar results were found with the isomer **61b** (25).¹⁰⁸

It is known that some vinyl radical intermediates are configurationally unstable, and from pure (*E*) or

(*Z*) substrate, the $S_{RN}1$ process yields a mixture of (*E*) and (*Z*) isomers.¹⁰⁴ The reaction of **61a** and **61b** with Me_3Sn^- affords only one isomer with retention of configuration, indicating that the inversion of these vinyl radical intermediates was slower than the coupling reaction of the radical with the Me_3Sn^- anion.¹⁰⁸

The stannanes thus obtained, such as the reactions of **62a**, can further react by Pd-catalyzed cross-coupling reaction with ArI to yield substituted alkenes **63** in high yields ($R = H, Me, OMe, Cl$, 87–98%) (26).¹⁰⁸

It has been reported that vinyl phosphate esters react with the Me_3Sn^- ion under irradiation to obtain vinyltrimethyl stannanes by the $S_{RN}1$ mechanism.¹⁰⁹ The reaction of Me_3Sn^- ions with 1-(diethoxyphosphoryl)oxy-1,3-cyclohexadiene **64** under irradiation affords the product **65** (59% yield) (27).¹¹⁰

However, the isomer 2-(diethoxyphosphoryl)oxy-1,3-cyclohexadiene reacts very slowly and no substitution product was identified. Thus, structurally similar compounds do not have the same reactivity. It is suggested that this behavior is mainly due to differences in the spin density of their radical anions, which influence their fragmentation rates.¹¹⁰

The $S_{RN}1$ mechanism has been proposed for the photoinduced catalytic carbonylation of vinyl bromides and chlorides with $NaCo(CO)_4$ under PTC conditions at atmospheric pressure, constituting a particularly interesting synthesis of unsaturated carboxylic acids.⁹³ Carbonylation can also be performed under atmospheric pressure of CO in the presence of a cobalt catalyst.¹¹¹

5 $S_{RN}1$ REACTIONS WITH ALIPHATIC SUBSTRATES

5.1 Cycloalkyl Halides

Substituted cyclopropanes react by the S_N1 mechanism through a disrotatory ring opening. This electrocyclic process has relatively high activation energy due to the fragmentation of two bonds in a concerted process. On the other hand, halocyclopropanes do not usually suffer nucleophilic substitution by the S_N2 mechanism. Instead, an elimination addition process occurs in the presence of strong bases.

In the reaction of carbanions with 7-iodonorcaradiene **66** (a mixture of circa 1:1 of *exo*:*endo* isomers), the substitution products **67** are 93–95% *exo* isomers, indicating that the coupling of the 7-norcaranyl radical with these carbanions is quite selective (28).¹¹² The same *exo* isomer yield (93–95%) obtained by reaction with $^-CH_2COPh$ ions initiated with inorganic salts ($FeBr_2$ or SmI_2)²³ evidences of the presence of 7-norcaranyl radicals as intermediates under both types of initiation.

Recently, the synthesis of new 1,1-bis(trimethylstannyl)cyclopropanes by the $S_{RN}1$ mechanism has been reported.¹¹³ 1,1-Dichlorocyclopropanes react under irradiation with the Me_3Sn^- anion in liquid ammonia to give the disubstitution products bis-stannylcyclopropanes in good to excellent isolated yield.

The photostimulated reaction of 2-iodoadamantane (2-AdI) with carbanions derived from MeCOPh, 2-naphthyl-methyl-ketone, *N*-acetylmorpholine, and anthrone affords substitution products in moderate yields (32–62%). The reaction with $^-CH_2COPh$ ions induced by $FeBr_2$ renders 88% substitution yield. The $^-CH_2NO_2$ anion reacts (in the presence of $^-CH_2COMe$ ions) to give 88% yield of substitution product.¹¹⁴

Excellent substitution yields are obtained with Me_3Sn^- ions and 2-AdCl (94%)¹¹⁵ and 2-AdBr

(80%) as substrates¹¹⁶ in liquid ammonia under irradiation.

5.2 Bridged Halides

Bridged halides have a high energy barrier for a S_N1 mechanism owing to strain factors and they do not react by the S_N2 mechanism for steric reasons. Many of these halides have been found to react by the S_{RN}1 mechanism.

1-Iodobicyclo[2.2.2]octane reacts with Ph₂P[−] ions in liquid ammonia under irradiation to give the corresponding substitution product (87% yield). The chloro derivative is unreactive under irradiation.¹¹⁷ However, 2-oxo derivative **68** (with a C=O π electron acceptor) reacts to afford 69% yield of product **71** (Scheme 13).¹¹⁸ This increase in reactivity has been explained by an intramolecular entrainment reaction. It is proposed that **68** receives an electron in its antibonding carbonyl π* MO to form the radical anion **69**, which by an intramolecular ET to the antibonding σ* MO of the C–Cl bond forms the bridgehead radical **70** that propagates the chain reaction.^{118,119}

Similarly, 1-chlorobicyclo[2.2.1]heptane is unreactive toward Ph₂P[−] ions; however, 1-chloro-3,3-dimethyl-2-oxobicyclo[2.2.1]heptane reacts to give, after oxidation, the substitution product (93% yield). 4-Chloro-1,7,7-trimethyl-2-oxobicyclo[2.2.1]heptane **72**, in which the spatial distance between the leaving group and the C=O π is

increased with an extra C–C bond, also affords the substitution products **73** (80% yield) (29).¹¹⁹

4-Halotricyclanes are one of the most unreactive substrates in solvolytic reactions. Yet, 4-iodotricyclane **74** reacts with Ph₂P[−] ions under irradiation to afford **75** in 58% yield (30). The 1-chloro derivative is totally unreactive.¹²⁰

Substrate **76** reacts with Ph₂P[−] ions under irradiation to afford the rearranged substitution product **77** (83% yield, as the oxide). The ET to **76** gives the bridgehead radical **78** after fragmentation. This radical rearranges by a 1,5-hydrogen shift to afford radical **79**, which couples with the Ph₂P[−] ion to give the substitution product **77** after oxidation (Scheme 14).¹²¹

1-AdI reacts under irradiation with carbanions derived from ketones in DMSO (20–75% yield).²⁹ These reactions can also be induced by FeBr₂. Thus, [−]CH₂COPh ions afford the substitution product in 85% yield.²³ 1-AdCH(NO₂)R is also formed by the photostimulated reaction of 1-AdI with [−]CHR(NO₂) anions (R = H, Me, C₅H₁₁, (CH₂)₃CH=CH₂, 77–87% yields) in the presence of [−]CH₂COMe in DMSO.¹²²

Other nucleophiles that also react with 1-haloadamantanes are Me₃Sn[−] (80% yield),¹²³ Ph₂P[−] (70% yield),¹²⁴ Ph₂As[−] (65% yield),¹²⁴ ArS[−] (45–95% yield),¹²⁵ PhSe[−] (74% yield),¹²⁶ and PhTe[−] (69% yield)¹²⁶ ions.

5-Bromoadamantan-2-one **80** reacts with LiSnMe₃ in THF to afford the substitution product **81** by a radical path; however, the iodo derivative furnishes the fragmentation product **82** by a polar reaction (31).¹²⁷

Scheme 13 Intramolecular redox catalysis in oxo derivatives of bridged halides.

Scheme 14 1,5-Hydrogen shift during an $S_{RN}1$ reaction.

When the substrate has two leaving groups, and one of them is iodine, such as **83**, the products obtained depend on the nature of the second halogen. Thus, with **83a** only substitution at iodine occurs (compound **84**, 63% yield). Both halogens are substituted with **83b** and **83c**, affording **85** in 83% and 58% yields, respectively (32).¹¹⁸

In the reaction of 1,3-dihaloadamantanes **86** with $M\text{SnMe}_3$ ($M = \text{Li}$ or Na), the products depend on the halogens. For example, when $X = \text{Cl}$ and $Y = \text{Br}$, the disubstitution product **87** is the main product (94–97% yield), whereas when $X = \text{Br}$, $Y = \text{I}$, or $X = Y = \text{I}$, propellane **88** is the major product (80–100% yield) (33). The $S_{RN}1$ mechanism accounts for **87**, but formation of **88** occurs

through a concerted process involving direct attack by the Me_3Sn^- ion on an iodine with synchronous cyclization and cleavage of the second $\text{C}-\text{X}$ bond.¹²⁸

In the photostimulated reaction of 1,3-dihaloadamantane with carbanions, the products also depend on the halogens. For instance, the photostimulated reaction of **89** ($X = \text{Br}$) with the $^-\text{CH}_2\text{NO}_2$ ion (and the $^-\text{CH}_2\text{COMe}$ ion as entrainment reagent) gives the disubstitution product **90** in 84% yield.¹²⁹ However, in the reaction with **89** bearing both iodo substituents, the rearranged monosubstitution product **91** is obtained in 87% yield (34).¹³⁰

When **89** ($X = \text{I}$) receives one electron, it fragments through a dissociative ET to give radical **92**

Scheme 15 Rearrangement of the monosubstitution S_{RN}1 product **94**.

that couples with the nucleophile to afford radical anion **93**, which, by an intermolecular ET to the substrate, affords substitution product **94** (Scheme 15). Compound **94** is deprotonated under the basic reaction conditions to yield carbanion **95**, which by a ring-opening reaction renders product **96**, in turn undergoing deprotonation to afford the carbanion **97**. After acidification, the most stable isomer **91** is obtained.¹³⁰

The fact that with 1,3-diiodoadamantane the intermolecular ET to the substrate to afford **94** as the intermediate is faster than the intramolecular ET to the other C–I bond accounts for the better electron acceptor capability of 1,3-diiodoadamantane as compared to the 1,3-dibromoadamantane.

CN[−] ions react in a photostimulated reaction (254 nm) with 1,3,5,7-tetrabromoadamantane **98**, affording tetrasubstituted product **99** in 73% yield by the S_{RN}1 mechanism (35).³²

5.3 Neopentyl and Related Halides

Several enolate anions such as [−]CH₂COMe ions fail to react with neopentyl bromide in liquid ammonia under irradiation. Reduction is the main reaction of neopentyl iodide in the presence of [−]CH₂COMe

ions in DMSO, whereas substitution is achieved with [−]CH₂COPh ions (65% under irradiation,¹³¹ 92% when initiated with FeBr₂²³). Substitution by [−]CH₂NO₂ ions also occurs (69%, in the presence of [−]CH₂COMe ions).¹³¹

PhS[−], Ph₂P[−], and Ph₂As[−] ions react with neopentyl bromide under irradiation with 60%, 76%, and 82% yields of substitution, respectively.¹³² The Na₂Se salt reacts with neopentyl iodide to give dineopentyl diselenide (83% yield) as a result of initial S_{RN}1 reaction and subsequent oxidation of the neopentyl selenide ion intermediate (36).¹³³

When MPPh₂ (M = Li, Na, or K) reacts with 6-iodo-5,5-dimethyl-1-hexene **100** in THF, the compounds indicated in (37) are formed by the S_{RN}1 mechanism.¹³⁴ The unrearranged **101** (17–43% yield), cyclized substitution **102** (48–75% yield), and cyclized hydrocarbon **103** (4–11% yield) products are obtained, and these yields depend on the counterion. The fact that rearranged products are obtained indicates that the radicals are intermediates.

Scheme 16 Neophyl rearrangement during the $S_{RN}1$ reaction of substrate **106**.

Recently, the reaction of a neopentyl chloride bonded to an oxazoline moiety **104** with Ph_2P^- ions by the $S_{RN}1$ mechanism has been reported to give the P–N ligand **105** with good yields (60–92% yield) (38). With these ligands **105**, new iridium complexes were synthesized and evaluated in the enantioselective hydrogenation of unfunctionalized olefins.¹³⁵

Neophyl iodide **106** reacts under irradiation with PhCOCH_2^- ions to afford the rearranged compounds **107** (50% yield) and **108** (16% yield), respectively.¹⁹ When **106** receives one electron, it fragments to afford radical **109**, which by a neophyl rearrangement gives radical **110**, which in turn reacts with the nucleophile to finally give **108** (Scheme 16).

Disubstitution at aromatic and aliphatic sites is achieved by the photostimulated reaction of $\text{CH}_2\text{CO}t\text{-Bu}$ and CH_2COPh ions with **111** (39).¹³⁶ In DMSO, the main reaction is $S_{RN}1$ to afford disubstitution **112** and rearranged disubstitution **113** products. In liquid ammonia, only substitution at the aromatic C-halogen site is observed

yielding **114**.

5.4 Perfluoroalkyl Halides

Perfluoroalkyl halides do not react by the S_N1 mechanism because of the low stability of perfluoroalkyl carbocations. They are precluded from undergoing S_N2 substitutions due to repulsion of the lone electron pairs of fluorine atoms to the backside attack by the nucleophile. However, R_fI are able to undergo a variety of nucleophilic substitutions by the $S_{RN}1$ mechanism. Some reactions occur in the dark and are accelerated by light, whereas others are induced electrochemically.

The reaction of the $\text{CMe}(\text{CO}_2\text{Me})_2^-$ ion with $n\text{-C}_8\text{F}_{17}\text{I}$ afforded only $n\text{-C}_8\text{F}_{17}\text{H}$ (27%).¹³⁷ These results seem to indicate that the $\text{CMe}(\text{CO}_2\text{Me})_2^-$ ion is able to transfer one electron to form radicals but is

unable to couple with the R_f radical. The reaction of primary R_fI with the [−]CMe₂NO₂ ion occurs under mild conditions to give R_fCMe₂NO₂ in ~80%.¹³⁸

The CF₃ moiety in carbonyl compounds are useful synthetic intermediates. However, defluorination is problematic under the basic conditions of S_{RN}1 reaction. This difficulty has been found in the radical trifluoromethylation of enolate ions, which is the most direct way to synthesize CF₃ carbonyl compounds. It has been recognized that the highly basic conditions with enolate ions could not be applied to the trifluoromethylation. The substitution product is deprotonated to give anion **115**, which loses a F[−] ion to give an unsaturated ketone **116** that decomposes very fast (40).

However, it has been found that the radical trifluoromethylation of the titanium ate enolate of ketone gives high yields of the products.¹³⁹ For instance, the titanium ate enolate cyclohexanone gave 81% yield of 2-(trifluoromethyl)cyclohexanone when treated with CF₃I and Et₃B to initiate the reaction. With only 1 equiv of lithium diisopropylamide (LDA) as base, it gave the same yield of the substitution product.¹⁴⁰ The radical trifluoromethylation of Ti ate and Li enolates has also been investigated by density functional theory (DFT) calculations.¹⁴¹

The radical trifluoromethylation of ammonium enolates derived from 1,3-dicarbonyl compounds with CF₃I in the presence of Na₂S₂O₄ to induce the reaction has been reported in MeCN–H₂O solution. The radical F₃C[•] is generated from the reduction of CF₃I with sulfur dioxide radical anion. Thus when substrates **117** were treated with a base and Na₂S₂O₄, products **118** were obtained (41).¹⁴²

The reaction of R_fI by electrochemical induction with several nitrogen nucleophiles is known to form a C–C bond with moderate yields. The reaction of uracil anion **119** with *n*-C₄F₉I, for instance, afforded the substitution product **120** in 65% yield (42).⁷³

The reaction of R_fI with chiral imide enolate ions induced by Et₃B and oxygen gives substitution products with good diastereoselectivity. For example, the reaction of anion **121** with *n*-C₆F₁₃I gives the product **122** (79% yield, de 71) (43).¹⁴³

R_fI has been found to react with ArS[−] ions under irradiation.^{144,145} In this system, the ArS[−] ion containing both electron-donating groups and EWGs is readily converted into ArSR_f in good yields. With a primary or secondary R_fI, the substitution affords 60–85% yield of the product, but while using a tertiary R_f no reaction occurs.¹⁴⁶

Iodide is not the only leaving group for such processes; it is known that bromo and chloro groups can also act as leaving groups. A series of chlorodifluoromethylated ketones react with ArS[−] ions to afford new α-(heteroarylthio)-α,α-difluoroacetophenone derivatives with moderate to good yields (44).¹⁴⁷

S_{RN}1 reaction of 2-(bromodifluoromethyl) benzoxazole **123** with a series of heterocyclic

thiolate ions^{148,149} and phenolic compounds¹⁴⁹ affords substitution products in variable yields. For instance, when **123** was allowed to react with ion **124**, compound **125** was obtained in 62% yield (45).¹⁴⁸

When **123** is allowed to react with ArO^- ions **126**, $\text{S}_{\text{RN}}1$ substituted products **127** are obtained from moderate to good yields (46).¹⁴⁹

Dichloride **128** reacts with PhS^- or PhO^- ions to afford the disubstitution product **129** (47).¹⁵⁰

In the reaction of bis-phenol **130** with NaH and **128**, a yellow solid is obtained in 81% yield, the structure of which is assumed to be the polymer **131** (48). The solid-state fluorine NMR spectrum indicates that it is a polymer of relatively uniform structure with a high molecular weight (36,000 g mol⁻¹).

Although this reaction occurs in the dark (70% conversion in 12 hours), under irradiation the reaction is accelerated (70% conversion in 3 hours) and inhibited by O_2 .¹⁵⁰

5.5 Alkyl Substrates with Electron-Withdrawing Groups

These types of compounds react through the $\text{S}_{\text{RN}}1$ mechanism with a great variety of nucleophiles centered on C, O, S, N, and P. In some cases, competition with other mechanisms, such as $\text{S}_{\text{N}}2$ or X-philic reactions, can take place, depending on the nature of the leaving group and the reaction conditions; however, it can be avoided via several approaches.⁵

5.5.1 α -Substituted Nitroalkanes and Other Activated Alkanes

Compounds of the $\text{X-CR}^1\text{R}^2\text{NO}_2$ type are the most extensively studied with a leaving group at an sp^3 carbon. Reactions where $\text{X} = \text{halides, ArS, ArSO}_2, \text{SCN, N}_3, \text{ and NO}_2$ have been reported. The NO_2 group can act as a leaving group not only in dinitro compounds but also when X is $\text{CN, COR, CO}_2, \text{R, Ph, or heteroaryl}$ (Scheme 17).

EWGs other than NO_2 have also been reported to activate haloalkanes in the α position (Scheme 18); reaction with different nucleophiles give the product of substitution of the halogen (Cl, Br) by the $\text{S}_{\text{RN}}1$ mechanism.^{5,151} For instance, *p*-cyano- and *p*-nitro-substituted α -haloisobutyrophenones react with $^-\text{CR}_2\text{NO}_2$ ($\text{R} = \text{alkyl, cycloalkyl}$), $^-\text{CR}(\text{CO}_2\text{Et})_2$, and $^-\text{CMe}(\text{CN})_2$ to give the substituted products in good yields (39–85%).

A variety of carbon nucleophiles react with this type of substrates, as in the case of anions derived

Scheme 17 Leaving groups in α -substituted nitroalkanes. Different behavior of NO₂ group in S_{RN}1 reaction.

Scheme 18 α -Activated alkyl substrates with EWGs other than NO₂.

from nitroalkanes, ketones, disubstituted carbanions (β -dicarbonylic, α -cyanoesters, and α -sulfonyl esters derivatives), and those derived from substituted heterocycles.

Anions from nitroalkanes are the most widely studied, and even the synthesis of cyclic compounds by intramolecular reaction has been performed. For example, from 1,4-naphthoquinone **132** obtained by an intermolecular photostimulated S_{RN}1 reaction (85% yield), a new substrate **133** is synthesized,¹⁵² and the photostimulated reaction **133** with MeONa allows the formation of **134** by an intramolecular S_{RN}1 cyclization (Scheme 19).

The synthesis of nitro compounds by this approach have synthetic utility, such as the synthesis of tri- and tetrasubstituted olefins through the elimination of NO₂⁻ ions. For example, the S_{RN}1 photostimulated reaction of substrate **135** with 2-nitropropane anion afforded **137** from **136** (Scheme 20).¹⁵³

Within the nitrogen nucleophiles, N₃⁻ ion is the most frequently used; however, important nitrogenated nuclei have also been employed, such as anions from imidazole, triazole, purines, and cytosine, among others.⁵ The S_{RN}1 reaction of

Scheme 19 Synthesis of cyclic compounds by an S_{RN}1 reaction.

2-bromo-2-nitropropane with the anion of thymine provides an interesting example in which the disubstituted product is obtained (64% yield) without any formation of the monosubstituted product (Scheme 21).¹⁵⁴

α -Substituted nitroalkanes react with alkoxide anions to give disubstituted compounds through an S_{RN}1 coupled to an S_{RN}1-like reaction (Scheme 22).⁵

P-centered anions (⁻PO(OR)₃, ⁻PS(OR)₃) react with α -substituted nitroalkanes to give the S_{RN}1 product in moderate to good yields. However, there are some examples in which competition with X-philic mechanism can be observed.⁵

5.5.2 Activated Benzyl Derivatives

Benzylic substrates which have an EWG attached to the phenyl ring react by S_{RN}1 reactions (Scheme 23).^{5,155} Although the NO₂ group is the best and the most largely used EWG to facilitate S_{RN}1 reactions, other groups such as CN, C(=O)Ph, and CF₃ also participate in these reactions. Depending on the type of substrate and nucleophile, the S_{RN}1 reaction can be in competition with the S_N2 process.

Reactions occur with various X leaving groups, and even groups that have very low reactivity or are unreactive in polar processes (S_N2) can act as leaving groups in S_{RN}1 reactions.

Although the EWG group facilitates the reaction, it has been established that such activation of the

Scheme 20 $S_{RN}1$ reaction followed by base-promoted NO_2^- ion elimination.

Scheme 21 Two consecutive $S_{RN}1$ reactions of 2-bromo-2-nitropropane with the anion of thymine.

aromatic ring is not necessary for the reaction to occur. The reaction of **138** with $^-\text{CH}_2\text{NO}_2$ ions nicely illustrates this (49)¹⁵⁶; good yield of the $S_{RN}1$ product (circa 84%) was obtained despite the slower rate of the reaction resulting from the absence of an EWG in the aromatic ring.

The most common is *p*-nitro substitution in such benzylic substrates; however, there are cases of substrates with ortho and meta NO_2 groups. In these two types of compounds, competition with S_N2 or other reactions are more important; yet, the

use of poor leaving groups and bulky groups in the α -carbon favors the $S_{RN}1$ route. For instance, the reaction of 2-nitropropane anion (50) with **139** ($R = \text{H}, X = \text{Cl}$) gave 32–45% yield of the $S_{RN}1$ product **140** and 52% yield of the S_N2 product **141**,⁶ and only the $S_{RN}1$ product (75% of the corresponding alkene after NO_2^- ion elimination) is found in the reaction with **139** ($R = \text{OMe}, X = \text{ArSO}_2$).¹⁵⁷

Scheme 22 S_{RN}1 coupled to an S_{RN}1-like reaction.

Scheme 23 Leaving groups (X) in activated benzylic substrates.

Carbanions derived from secondary and tertiary nitro compounds have been used in the reaction with *p*-nitro benzyl and cumyl derivatives to study the regiochemistry of the coupling of the radical with the nucleophile. In addition, the use of more complex nitro compounds derived from carbohydrates allows the synthesis of the corresponding alkylated nitro compounds in moderate to good yields.⁵

An interesting example of the scope of these reactions is the photostimulated reaction of ethyl 2-nitropropionate anion with *p*-nitrobenzyl chloride **142** to give the S_{RN}1 product **143**, which after reduction delivers the α -amino acid **144** (51).¹⁵⁸

Carbanions from β -dicarbonyls, β -dinitriles, α -cyano esters, uracil derivatives,⁵ and CN⁻ ions¹⁵⁹ have also been used in S_{RN}1 reactions with *p*-nitrobenzyl and cumyl derivatives to give the corresponding products with good yields. The nitrogen nucleophiles that react with *p*-nitro benzyl and cumyl derivatives are N₃⁻, NO₂⁻, as well as anions from imidazoles, benzimidazoles, and pyrazoles (26–100% yield). Neutral primary, secondary, and tertiary alkyl amines also react to give the products with good yields (66–96% yield). In a study of the base-promoted reaction of amine **146** with α -*p*-dinitrocumene **145**, the product of *N*-alkylation was obtained (**52**); it was concluded that the mechanism was partly S_{RN}1.¹⁶⁰

p-Nitrocumyl derivatives react with RO⁻ ions through an S_{RN}1 reaction to give the substituted products with a C–O bond formation. The reaction of MeO⁻, PhO⁻, and 1-methyl-2-naphthoxide ions with *p*-nitrocumyl derivatives allows the preparation of ethers (56–69% yield).⁵

Scheme 24 Intervening mechanisms in the formation of product **150** from **142** and $(\text{RO})_2\text{PO}^-$ anions.

Anions derived from thiols, 2-mercaptoazoles, and ArSO_2H also react with *p*-nitrobenzyl derivatives through an $\text{S}_{\text{RN}}1$ mechanism and good yields of the products are obtained (36–96% yield).^{5,159} However, with *p*-nitrobenzyl derivatives, the mechanism depends on the nucleophile used, in spite of the fact that the products obtained are the same.¹⁶¹

It is known that anions of phosphorus [$(\text{RO})_2\text{PO}^-$, $(\text{RO})_2\text{PS}^-$] react with *p*-nitrobenzyl halides through different mechanisms: $\text{S}_{\text{RN}}1$, $\text{S}_{\text{N}}2$, X-philic attack, and deprotonation to form benzyl anions; as a consequence, different products could be obtained depending on the conditions used. *p*-Nitrobenzyl chloride **142** reacts with $(\text{RO})_2\text{PO}^-$ ($\text{R} = n\text{-alkyl}, i\text{-propyl}, \text{Ph}$) in DMSO through the $\text{S}_{\text{N}}2$ mechanism to give the product **148**; however, an $\text{S}_{\text{RN}}1$ reaction takes place in THF or EtOH to give **148** in a photostimulated reaction.¹⁶² Carbanions **149** are formed *in situ* in the reaction described above in DMSO, and the disubstitution products are obtained in a photostimulated $\text{S}_{\text{RN}}1$ reaction (Scheme 24).¹⁶² The hindered $(t\text{-BuO})_2\text{PO}^-$ anion reacts with **142** in DMSO mainly through $\text{S}_{\text{RN}}1$, but as competition deprotonation of **142** occurs.¹⁶³

The bromide analog of **142** reacts by an X-philic mechanism to give the *p*-nitrobenzyl anion. The anions thus generated may react in some cases to di(*p*-nitrobenzyl) via an $\text{S}_{\text{RN}}1$ reaction with the substrate.¹⁶³

5.5.3 Heterocyclic Analogs of Benzyl Substrates

Various heterocyclic analogs of the benzyl derivatives react with nucleophiles through an $\text{S}_{\text{RN}}1$ reaction. Imidazoles are one of the most extensively studied and allow the preparation of new 5-nitroimidazoles and 5-nitro-1,2-fused-imidazoles bearing tri- or tetrasubstituted alkenes with good yields.^{5,164}

Methyl oxazoles and thioxazoles activated with a tetrasubstituted *p*-benzoquinone ring **151a** react by the $\text{S}_{\text{RN}}1$ mechanism to give substitution products **152a** with good yields (53). However, *N*-methylimidazole **151b** does not react under the same condition, a behavior that has been ascribed to the lack of coplanarity of the two rings due to the methyl group.¹⁶⁵

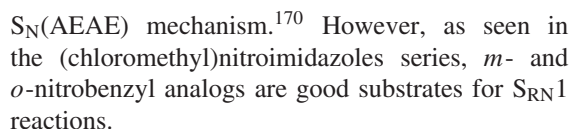

(53)

These analyses were confirmed by reaction of fused oxazoles and imidazoles that smoothly react

Competition with another mechanism can occur; for instance, 2-(halomethyl)-5-nitrofurans give substitution with $^-CMe_2NO_2$ ions by the $S_{RN}1$ pathway,¹⁶⁷ whereas they react by S_N2 with various RS^- ions.¹⁶⁸ Again, substitution at the benzylic carbon and poorer leaving groups favor the $S_{RN}1$ mechanism; the reaction of nitrofurans **153** and **154** with benzenesulfinate ions (54) clearly illustrates this.^{168,169}

Nitroanions are the nucleophiles most extensively studied and give the corresponding olefins as the final products under classical reaction conditions (Scheme 25).^{5,153,171,172}

Carbanions from aliphatic, cyclic, heterocyclic, functionalized nitroalkanes, and 3-nitrolactams have also been used as nucleophiles.

Recently, an $S_{RN}1$ reaction promoted by microwave irradiation allowed the preparation of quinazoline derivatives starting from 2-chloromethyl-3-methyl-6-nitroquinazolin-4(3*H*)-one and nitronate anion.¹⁷³ The products were obtained in yields higher than those found under classical conditions.

In addition to nitronate anions, other nucleophiles, such as carbanions from β -diesters, 4-hydroxycoumarin, PhCH_2S^- , and PhSO_2^- ions, have been used mainly in the synthesis of pyrimidinones.¹⁷⁴

The position of the nitro group influences the competitive mechanism; for example, 5-nitro-2-(halomethyl)-thiophenes react by $S_{RN}1$; conversely, its 4-nitro analogs react by an

Scheme 26 Synthesis of 2,3,6,7-tetralkylantraquinones.

5.5.4 Other Activated Benzyl Halides

2,3-Bis(chloromethyl)-1,4-naphthoquinone reacts with the 2-nitropropane anion by the $S_{RN}1$ mechanism to give the disubstituted product **156**. After ring closure, compound **157** is obtained in good yield (55).¹⁷⁵

An interesting one-pot synthesis of dialkyl-substituted anthraquinones was conducted by this procedure using primary nitronate anions, which consists of two consecutive $S_{RN}1$ processes followed by base-promoted nitrous acid elimination, electrocyclic ring closure, and dehydrogenation. This new annulation method was also applied to synthesize dialkynaphthacene-5,12-di-ones and 1,4-naphthoquinones with acceptable yields.¹⁷⁵ The use of tetrachloride benzoquinone with nitronate

anion allows the preparation of the tetra-alkylated product after four consecutive $S_{RN}1$ reactions. The synthesis of 2,3,6,7-tetralkylantraquinones (40–46% yield) was achieved using the procedure described above (Scheme 26).

The reaction of 2-fluoromethyl-3,5,6-trimethyl-1,4-benzoquinone with the $^-CMe_2NO_2$ ion is the first example of displacement of F by $S_{RN}1$ at an sp^3 carbon.¹⁷⁶ The C-alkylation product was obtained in good yield (70%). Difluoride analogs **158** also react by the $S_{RN}1$ mechanism affording the monofluoro-product in good yields (56).¹⁷⁷ The high yield of the monosubstitution product **159** as compared to the disubstituted one can be explained on the basis of the high stability of the radical anion of the product due mainly to the nitro group.

Other benzyl dihalides and analogs have been studied in the reaction with nitronate anions. For instance, *p*-nitrobenzylchloride reacts with the $^-CMe_2NO_2$ ion by an $S_{RN}1$ reaction, followed by an $E_{RC}1$ to give a mixture of products.⁵

Trichloromethyl 5-nitroimidazoles have been used to prepare derivatives bearing a tetrasubstituted double bond in moderate to good yield by reaction with nitronate anions.¹⁷⁸ As in the case

of dihaloderivatives, the reaction occurs by S_{RN}1 followed by E_{RC}1 reactions.

5.5.5 Activated Allyl Derivatives

Allyl systems substituted with *p*-nitrophenyl moiety react with different carbanions through various mechanisms: S_{RN}1, S_N2, and S_N2'. As we have already seen for other systems, the reaction outcome depends on the substrate and conditions. Thus in the series of compounds **160**, the S_{RN}1 component becomes more important for substrates bearing sterically hindered R substituents (57).^{179,180}

An interesting example of the application of these types of substrates in S_{RN}1 reaction is the synthesis of prostaglandin (PGB₁) analogs from 3-substituted-2-(phenylsulfonylmethyl) cyclopenta-2,4-dienone **161** (58).¹⁸¹

Other type of substrates studied involve α -substituted 3-cyclohexenones and mono and dichloride 5-nitroimidazoles, which react by various mechanisms in addition to S_{RN}1.⁵

6 CONCLUSION

The coupling between radicals and nucleophiles is a broad and general reaction. Reactions occur with

aryl, vinyl, and aliphatic radicals without EWGs (cycloalkyl, bridgehead, and neopentyl radicals), as well as perfluoroalkyl and alkyl radicals with EWGs at the α carbon. With the exception of substrates with EWGs in the α carbon, these radicals are derived from substrates that do not react or react slowly by polar mechanisms. We propose that any other substrates with the same reduced reactivity toward nucleophiles would also react by the S_{RN}1 mechanism.

The nucleophiles able to react with these radicals are carbanions and those with heteroatoms such as derivatives of Sn and elements from the 15 (N, P, As, and Sb) and 16 (O, S, Se, and Te) groups.

The monosubstitution product is not the only possible product to obtain, di-, tri-, and even tetrasubstitution with substrates bearing more than one leaving group is also viable.

One of the most widely studied approaches to ring-closure reactions is the S_{RN}1 substitution of aromatic compounds that have an appropriate substituent Z ortho to the leaving group, which can react with a nucleophile Nu to afford the substitution product. The ring-closure product is achieved by the spontaneous reaction between the Nu group and Z.

In an adequate distance with an appropriate combination of leaving groups and nucleophilic centers in the same molecule, the intramolecular synthesis of heterocycles can be achieved. The radical intermediates can also be trapped by an appropriate double bond, and the resulting radical intermediates can react with a nucleophile to give substituted heterocycles.

All these mechanistic possibilities open a wide area in physicochemical and synthetic organic chemistry.

Halogen and Chalcogen Transfer Chemistry

Chaozhong Li

Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, Shanghai, People's Republic of China

1 INTRODUCTION

Atom transfer reactions have emerged as one of the most important tools in the field of free-radical chemistry. The discovery of atom transfer reactions can be traced back to the year 1945 when Kharasch *et al.* reported the addition of CCl_4 to 1-octene in the presence of a catalytic amount of radical initiators.¹ A few years later, the Kharasch group showed that, with diacetyl peroxide as the initiator, ethyl bromoacetate was added to 1-octene to give the bromine atom transfer product ethyl 4-bromodecanoate upon thermolysis.² As a result, atom transfer radical addition (ATRA) is also called *Kharasch addition*. These studies did not receive much attention until the mid-1980s when Curran *et al.* first demonstrated the atom transfer radical cyclization (ATRC) reactions³ and their application in the synthesis of ($\pm$)-hirsutene.⁴ These works significantly encouraged further study in this type of transformations and enormous progress has been achieved ever since. Reactions involving transfer of halogens (I, Br, Cl) and chalcogens (SePh and TeAr) have been developed.⁵ This concept has been extended to atom transfer radical polymerization (ATRP), which has become an area of intensive research in recent years (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**). In a broader sense, atom transfer reactions encompass radical

addition reactions in which carbon–heteroatom or heteroatom–heteroatom bonds add across $\text{C}=\text{C}$, $\text{C}\equiv\text{C}$, or other multiply bonded functionalities. In this article, we focus on the halogen and chalcogen transfer reactions involving carbon–carbon bond formation. The xanthate transfer chemistry is not included, which is discussed in other articles of this encyclopedia (see **Xanthates and Related Derivatives as Radical Precursors and Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**).

2 MECHANISTIC CONSIDERATION

The mechanism shown in Scheme 1, originally proposed by Kharasch *et al.*,² represents the generally accepted mechanism for most atom transfer addition reactions. Once the substrate radical is initiated, it adds to 1-octene to give the adduct radical. The adduct radical abstracts the bromine atom of the substrate (ethyl bromoacetate) to give the ATRA product and another substrate radical, which then enters into the next circle. The overall reaction generates a new $\text{C}-\text{C}$ σ bond at the expense of the breakage of a $\text{C}-\text{C}$ π bond, providing the driving force for the chain process. All the atoms in the starting bromide and alkene are present in the product molecule,

Scheme 1 The typical mechanism for atom transfer radical addition.

making the transformation highly atom-economic in nature.

To have a successful atom transfer reaction, the following criteria should be satisfied. First, the carbon–heteroatom bond in the substrate should be relatively weak in order to facilitate initiation. Initiation can occur either thermally in the presence of a suitable initiator or under direct ultraviolet (UV) photolysis, depending on the substrate structures (see **Overview of Radical Initiation**). The most commonly used initiation system is the use of $(\text{Bu}_3\text{Sn})_2$ under sunlamp irradiation.³ While the tributyltin radical might be involved in the initiation step, the more critical role of $(\text{Bu}_3\text{Sn})_2$ is probably to scavenge radical chain suppressants such as I_2 .⁶ Another widely used initiator is BET_3/O_2 , the active species being the ethyl radical.⁷ Other initiators include diazo compounds such as 2,2'-azobis(2-methylpropionitrile) (AIBN), peroxides such as benzoyl peroxide (BPO), and even arenediazonium salts/ TiCl_3 .⁸

The second and also the most important requirement is that the adduct radical should abstract a heteroatom from the substrate (to give atom transfer product) much faster than its addition to an olefin (to give telomers). Indeed, the atom transfer step is quite fast in most successful ATRA reactions. A clear understanding on the rates of heteroatom abstraction of various alkyl radicals is thus essential in the design of ATRA reactions. An extensive list of rate constants for homolytic substitution reactions by alkyl radicals on a variety of alkyl halides and chalcogenides is now available in the literature.⁹ A typical set of rate constants is as follows. The rate constants for the halogen atom or aryl chalcogen

(X) transfer from $\text{XCH}_2\text{CO}_2\text{Et}$ to a primary alkyl radical in benzene at 50°C have been measured by Curran *et al.* to be about 7×10^4 (for Br), 1×10^5 (for PhSe), 2.3×10^7 (for PhTe), and 2.6×10^7 (for I) $\text{M}^{-1} \text{s}^{-1}$.¹⁰ These data reflect the general reactivity pattern in atom transfer reactions. On the other hand, the corresponding Cl atom or PhS group transfer occurs at a much slower rate^{10,11} and their use in ATRA reactions via the mechanism shown in Scheme 1 is not commonly observed.

Finally, the carbon–heteroatom bond formed in the product should be stronger than that broken in the reactant. This allows the chain-propagating steps to proceed as planned by selectively abstracting the heteroatoms from the substrate rather than from the product. As a result, the atom transfer product remains relatively stable under the reaction conditions. This difference in bond dissociation energy also provides an additional driving force for the atom transfer reactions.

Compared to the reductive radical addition processes typically mediated by tin hydride, the nonreductive ATRA is advantageous in that reactions involving slow olefin addition steps can proceed. The addition of substrate radical to a $\text{C}=\text{C}$ bond has only to be faster than radical–radical or radical–solvent reactions, and this can be easily met when the reactions are carried out in inert solvents such as benzene or dichloromethane. On the other hand, reductive radical addition reactions always suffer from the direct reduction of substrate radicals because of their fast H abstraction from tin hydride, especially when the radical addition is slow (see **Tin Hydrides and Functional Group Transformations**).

Scheme 2 The mechanism for transition metal-catalyzed chlorine atom transfer radical addition.

The radical addition step in atom transfer reactions is governed by the combination of steric and electronic effects as usual.¹² While nucleophilic alkyl radicals pair with electron-deficient alkene acceptors,¹³ electrophilic radicals such as malonyl radicals pair with electron-rich alkene acceptors in radical addition reactions. The latter case is more common in atom transfer reactions because the C–X bonds become weaker with one or more electron-withdrawing substituents. Steric factors may sometimes predominate in controlling the radical reactions. For example, malonyl radicals add faster to 1-octene than to the more electron-rich tetramethylethylene.¹⁴

While chlorine atom transfer is rare in the above ATRA processes, it can be successfully implemented with the help of a suitable transition metal catalyst.¹⁵ This process, however, takes place via a different mechanism, as shown in Scheme 2. The catalytic circle starts with the homolytic cleavage of an alkyl chloride by a transition metal complex in the lower oxidation state ($M^{n+}L_m$) to generate an alkyl radical and the corresponding metal chloride in the higher oxidation state ($M^{n+1}L_mCl$, see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**). The radical adds to an alkene to give the adduct radical, which is then trapped by the transition metal chloride in the higher oxidation state, which is a much more effective chlorine atom transfer agent than the substrate alkyl chloride, to afford the ATRA product. In the meantime, the transition metal complex in the lower oxidation state is regenerated and therefore enters into the next catalytic circle. Similar to the atom transfer process depicted in Scheme 1, this transition-metal-catalyzed process requires that (i)

the adduct radical is quenched by $M^{n+1}L_mCl$ at a much faster rate than its addition to another molecule of alkene and (ii) further activation of the product chloride should be avoided. The difference between the conventional ATRA and the transition-metal-catalyzed one is that the transition metal catalyst functions as both the radical initiator and the mediator for chlorine atom transfer in the latter case. A number of transition metals such as Cu,¹⁶ Fe,¹⁷ Ru,¹⁸ and Mn¹⁹ have been developed for these transformations.

3 IODINE ATOM TRANSFER

Iodine atom transfer reactions are the most commonly studied type of reactions because of their easy initiation, the fast rate of iodine atom transfer, and the ready availability of alkyl iodides.

The first example of iodine ATRA reactions is the addition of perfluoroalkyl iodides to alkenes.²⁰ With the initiation of AIBN, perfluoroalkyl iodides add across monosubstituted alkenes in excellent yields, as shown in Scheme 3. The reactions can also be performed in hexane with Et_3B as the initiator, and allow the use of 1,2-disubstituted alkenes as the radical acceptor.²¹ In the presence of a base such as 2,6-lutidine, the reactions of perfluoroalkyl iodides with silyl enol ethers followed by treatment with aqueous HCl afford α -perfluoroalkyl ketones in good yields (Scheme 3).²² In contrast, ordinary alkyl iodides are not suitable for the ATRA reactions with alkenes. However, both ordinary alkyl iodides and perfluoroalkyl iodides can participate in the ATRA reactions with alkynes. Treatment of perfluoroalkyl iodides with terminal or internal acetylenes bearing a variety of substituents in the presence of a catalytic amount of Et_3B provides the corresponding perfluoroalkyl-substituted alkenes in high yields with an excellent *E*-stereoselectivity (Scheme 3).²¹ In a similar manner, secondary or tertiary alkyl iodides also undergo ATRA reactions with terminal acetylenes to give the corresponding alkenyl iodides in good yields with variable stereoselectivities, depending on the substrate structures.⁷ Exclusive *Z*-alkenes can be achieved in the cases of trimethylsilylacetylene, which may be attributed to the isomerisation of *E*-isomer to *Z*-isomer under the reaction conditions (Scheme 3).

Scheme 3 Iodine ATRA reactions of perfluoroalkyl and alkyl iodides.

Scheme 4 Iodine ATRA reactions of alkyl iodides with CO.

In addition to alkenes and alkynes, carbon monoxide can also be employed as radical acceptor in the ATRA reactions with alkyl iodides.²³ Ryu have shown that the photoinduced reactions of RI, CO, and alcohols or amines provide the corresponding aliphatic carboxylic acid esters or amides (Scheme 4).²⁴ The atom transfer carbonylation proceeds efficiently with secondary and tertiary alkyl iodides, whereas a longer time of reaction is required for primary alkyl iodides. These processes can be effectively accelerated by photosensitizers²⁵ or by transition metal complexes such as $\text{Pd}(\text{PPh}_3)_4$.²⁶ As an example, the $\text{Pd}(\text{PPh}_3)_4$ -catalyzed irradiation of pent-4-enyl iodide with CO and butanol affords butyl 2-(2-oxocyclopentyl)acetate in 82% yield via the carbonylation–cyclization–carbonylation sequence (Scheme 4).

A large number of iodine atom transfer reactions involve the use of alkyl iodides with one or more adjacent carbonyl or nitrile substituents. The electron-withdrawing α -substituent lowers the C–I bond dissociation energies in the substrates, thereby facilitating the radical initiation and allowing the atom transfer step to be exothermic. Two typical examples of intermolecular iodine atom transfer addition to alkenes are listed in Scheme 5. With 5 mol% of dilauroyl peroxide (DLP) as the initiator, the reaction of ethyl iodoacetate with 1-octene in refluxing benzene affords the desired ATRA product in 93% yield.²⁷ A variety of substituted α -iodo esters, amides, nitriles, and sulfones can be utilized in these ATRA reactions. The alkenes are typically limited to mono- and disubstituted electron-rich alkenes. A number of functional groups such as –OH, OAc, and so on, can be well tolerated under

Scheme 5 Iodine ATRA reactions of alkyl iodides to alkenes.

the experimental conditions. $\text{Et}_3\text{B}/\text{O}_2$ can also be employed as the initiator.²⁸ These reactions can also be successfully carried out either in aqueous media with $p\text{-MeOC}_6\text{H}_4\text{N}^+\text{BF}_4^-/\text{TiCl}_3$ as the initiator⁸ or neat in the presence of copper powder.²⁹ The reactions of iodoacetic acid or iodoacetamide with alkenols in water under the initiation of water-soluble 4,4'-azobis(4-cyanopentanoic acid) (V-501) afford the corresponding γ -lactones in high yields (Scheme 5).³⁰ Similarly, reactions of iodine atom transfer addition to alkynes can be successfully implemented in high efficiency.^{31,32}

Iodomalonates or malononitriles are particularly reactive in ATRA reactions because of their weak C–I bonds and the high electrophilicity of the substrate radicals. They undergo efficient ATRA reactions with mono- or disubstituted alkenes via simple heating in the dark or in the presence of catalytic $(\text{Bu}_3\text{Sn})_2$ under sunlamp irradiation.^{33,34} The addition of methyliodomalononitrile to

dialkyl-substituted alkenes can be diastereoselective in some cases, depending on the size of the alkyl substituents, as shown in Scheme 6.³⁴ When allyl- or propargyliodomalonates are used, annulated products are formed.³⁵ The more reactive iodomalononitriles also add to trisubstituted alkenes upon heating in benzene. Further treatment with tin hydride affords the corresponding reduction products in good yields (Scheme 6).

Perhaps the most exciting characteristic of atom transfer reactions is atom transfer cyclization. Curran's pioneering work in this area has not only demonstrated the potential of atom transfer cyclization in organic synthesis but also paved the ground for further research in ATRC reactions. One famous example is the synthesis of ($\pm$)-hirsutene shown in Scheme 7.⁴ The reaction can be extended to the 5-exo cyclization of alkenyl or alkynyl iodides.^{3,7,36,37} Good to excellent *E*-stereoselectivity is observed in the ATRC

Scheme 6 Addition and annulation reactions of malonates and malononitriles.

Scheme 7 Iodine ATRC of alkyl iodides.

Scheme 8 Unimolecular chain transfer reactions of silicon hydrides.

reactions of alkyl iodides with terminal alkynes. For internal alkynes, the stereochemical outcome depends heavily on the alkyne substituents. Increasing the size of the substituent decreases the *E*-selectivity. When the starting alkynyl iodides are (prop-2-ynyl)silanes, the vinyl radicals generated via the initial 5-exo cyclization are quenched by intramolecular 1,5-hydrogen abstraction to afford the *E*-alkenes exclusively (Scheme 8).³⁸ These unimolecular chain transfer (UMCT) reactions³⁹ are advantageous over the analogous bimolecular chain reactions with Bu_3SnH in the control of stereoselectivity.

Alkyl iodides also undergo ATRC reactions with aromatic rings. An interesting example is the intramolecular aryl migration from tin to carbon via atom transfer cyclization reported by Oshima *et al.* (Scheme 9).⁴⁰ Upon initiation with Et_3B , the alkyl radical adds to the aromatic ipso-carbon in a 5-exo-like mode to give the cyclohexadienyl radical, which then undergoes $\text{Sn}-\text{C}$ bond cleavage to afford the stannyl radical. The stannyl radical then abstracts an iodine atom from another substrate

molecule to provide the stannyl iodide as the ATRC product in a high yield.

The atom transfer cyclization of α -carbonyl radicals has received considerable attention in the past two decades because of their versatility in the synthesis of functionalized carbo- and heterocycles of various sizes. A simple model is hex-5-enyl iodide bearing a 1-ester or carbonyl substituent (Scheme 10).^{41,42} The radical cyclization is kinetically controlled and irreversible.⁴¹ The α -ester radicals cyclize predominantly via the 5-exo mode. The regioselectivity is lowered when the α -ester radical is switched to an α -keto radical. Moreover, the endo mode becomes significantly preferred in the cyclization of α -keto radicals in which the carbonyl group is oriented inside the forming ring. For example, the reaction of 1-iodohex-5-en-2-one affords exclusively the 6-endo cyclization product (Scheme 10). Substituent effects also play a key role in controlling the regioselectivity of cyclization. For example, the malonyl radical adds to the cyclohexene moiety via the 5-exo mode, as shown in Scheme 11.⁴¹ On the other hand, the cyclization of

Scheme 9 Intramolecular aryl migration from tin to carbon.

Scheme 10 ATRC reactions of α -iodoesters and ketones.

Scheme 11 Substituent effects in 5-exo versus 6-endo cyclization of malonyl radicals.

2-(4-methylpent-4-enyl)malonate proceeds via the 6-endo mode only (Scheme 11). As an extension, similar results can be obtained in the analogous 6-exo versus 7-endo cyclization reactions.⁴¹ It is worth mentioning that the stereoselectivity is typically poor in these cyclization reactions (Scheme 10). Nevertheless, stereoselective cyclization can be achieved in some cases, depending on the substrate structures.

Iodine atom transfer cyclization of α -ester or α -carbamoyl radicals also provides unique access to lactones or lactams of various sizes. *N,N*-Diallyliodoacetamide undergoes efficient ATRC at room temperature to afford the corresponding 5-exo cyclization product in almost quantitative yield.^{43,44} However, the sunlamp irradiation of allyl iodoacetate in the presence of catalytic $(\text{Bu}_3\text{Sn})_2$ at room temperature fails to give any expected cyclization product (Scheme 12).⁴³ These different behaviors should be attributed to the preferred *s*-trans conformations of esters and amides, whereas the 5-exo cyclization requires the *s*-cis conformation of the substrate radical. The energy barriers for the interconversion between *s*-trans and *s*-cis conformations are relatively high

for typical esters ($\sim 13 \text{ kcal mol}^{-1}$)⁴⁵ and amides ($16\text{--}22 \text{ kcal mol}^{-1}$).⁴⁶ The efficient cyclization of *N,N*-diallyliodoacetamide is due to the fact that the two rotamers are identical, and one of the allyl groups is always properly oriented for cyclization. On the other hand, the radical derived from allyl iodoacetate at room temperature is exclusively in the *s*-trans conformation and its lifetime is probably too short to surmount the barrier for ester bond rotation to the *s*-cis conformation. As a result, radical oligomerization rather than cyclization occurs.⁴⁷

In order to achieve efficient cyclization, several methods have been developed. Curran and Tamine have demonstrated that, by increasing the reaction temperature from room temperature to 80°C , the yield of the 5-exo cyclization product of allyl iodoacetate is increased from 0 to 41% (Scheme 12).⁴³ It is obvious that the ester bond rotation speeds up at higher temperature, allowing the substrate radical to adopt the *s*-cis conformation within its lifetime. The 5-exo cyclization then rapidly follows. In a similar manner, the ATRC reaction of *N*-allyl-*N*-methyliodoacetamide affords the 5-exo cyclization product in 87% yield at 80°C ,

Scheme 12 5-exo Cyclization of allyl iodoacetate.

while only 39% yield is obtained at room temperature. An alternative method for the cyclization of α -carbamoyl radicals is to attach a bulky group such as the *tert*-butyl group to the amide nitrogen, thus locking the substrates in the conformations prone to cyclization.

Substrate concentrations are also an important factor. Barth and O-Yang have shown that, when the concentration of allyl iodoacetate is decreased from 0.5 to 0.008 M, the yield of the 5-exo cyclized product can be improved from 11 to 64%.⁴⁷ Apparently, the lower concentration suppresses the intermolecular addition, while the intramolecular addition is not affected much by the change of concentration.

Solvents also play an important role in ATRC reactions of α -ester radicals. Oshima *et al.* have demonstrated that, when the Et₃B-induced ATRC reaction of allyl iodoacetate is performed in water at room temperature, the cyclized product is achieved in 67% yield (Scheme 12).⁴⁸ This is in sharp

contrast to the reaction in benzene at room temperature (0% yield of cyclization product). Further *ab initio* calculations have revealed that the large dielectric constant of water reduces the barrier to ester bond rotation to make rotation easier than in benzene. In the meantime, the activation energy for 5-exo cyclization is also lower in water than in benzene. Thus, radical cyclization becomes efficient in water even at room temperature.

In addition to the above temperature, concentration, and solvent effects, Lewis acids also play a vital role in the cyclization of α -ester or α -carbamoyl radicals.⁴⁹ α -Carbonyl radicals are ambiphilic in character.⁵⁰ The coordination of α -carbonyl radicals to Lewis acids significantly increases their electrophilicity, making their rates of addition to unactivated alkenes higher. In the meantime, the coordination of Lewis acids may help in directing the substrates to adopt the conformations required for cyclization. In addition, the coordination of Lewis acids to carbonyls makes

Scheme 13 Lewis acid-promoted cyclization of α -ester radicals.

Scheme 14 Lewis acid-promoted cyclization of α -carbamoyl radicals.

the initiation of α -carbonyl radicals much easier by lowering the C–I bond dissociation energies. For example, the sunlamp irradiation of but-3-en-1-yl 2-iodoalkanoates with catalytic $(\text{Bu}_3\text{Sn})_2$ at room temperature offers no desired 6-exo cyclization product. However, with the presence of excess $\text{BF}_3 \cdot \text{OEt}_2$, the reactions proceed smoothly at room temperature to give the cyclized products in good yields (Scheme 13).⁵¹ Good to excellent stereoselectivities in favor of the cis isomers are observed. *Ab initio* calculations at the UB3LYP/6-31G* level on the cyclization reveal that the reactions are kinetically controlled and the transition states for the 6-exo cyclization are in boat conformations. Moreover, the cis-oriented transition states are of lower energy than the corresponding trans-oriented ones, resulting in the unique cis-stereoselectivity in the tetrahydropyran-2-one products. The effect of $\text{BF}_3 \cdot \text{OEt}_2$ can also be found in the 8-endo ATRC reactions of 4-pentenyl iodoacetates. The cyclization proceeds regioselectively at room temperature with the promotion of $\text{BF}_3 \cdot \text{OEt}_2$ to afford the expected 5-iodooxocan-2-ones in high yields.⁵² This ATRC method is advantageous over the reductive cyclization method with Bu_3SnH in that a significant amount of the uncyclized reduction products is always observed in the latter case.⁵³

The Lewis acid effect is even more crucial in promoting the cyclization of α -carbamoyl radicals.^{54,55} As shown in Scheme 14, the $\text{Et}_3\text{B}/\text{O}_2$ -initiated reaction of *N*-acyloxazolidinone substrate at room temperature gives the corresponding 8-endo ATRC product azocan-2-ones in 50% yield as a mixture of two stereoisomers, both having the 3,8-trans configuration. On the other hand, with the presence of $\text{Mg}(\text{ClO}_4)_2$ (150 mol%) and the bis(oxazoline) ligand **L** (150 mol%), the reaction proceeds at room temperature to afford exclusively the third isomer with 3,8-cis configuration in 72% yield.⁵⁵ The addition of the Lewis acid not only improves the yield of the cyclized product but also changes the stereoselectivity of cyclization. In addition, the I abstraction step also becomes stereoselective. Further density functional calculations at the UB3LYP/6-31G* level indicate that the 8-endo cyclization proceeds via the s-trans conformational transition states in the absence of a Lewis acid. On the other hand, with the Lewis acid able to form chelation with the substrate, cyclization takes place via the fixed s-cis conformational transition states. In both cases, 8-endo cyclization is fundamentally preferred over the corresponding 7-exo cyclization. Moreover, the chelation of Lewis acid to the substrate significantly decreases the activation

Scheme 15 Enantioselective iodine transfer radical cyclization.

Scheme 16 Oligomerization of allyl iodoacetate followed by deoligomerization.

energy of cyclization from ~ 14 to ~ 7 kcal mol $^{-1}$, resulting in the higher efficiency of cyclization. In the meantime, the more rigid structure by complexation also makes the I abstraction stereoselective. The Lewis acid effect also allows the direct competition between 5-exo and 8-endo cyclizations of α -carbamoyl radicals via fixed s-trans- or s-cis conformations. The results shown in Scheme 14 indicate that 8-endo cyclization is quite competitive to the common 5-exo cyclization for α -carbamoyl radicals even when the substrate conformations are fixed as s-cis. On the other hand, when the substrate conformations are fixed as s-trans, as in the case of *N*-(hepta-1,6-dien-3-yl)-2-iodoacetamide, only 8-endo cyclization occurs (Scheme 14).^{54–56}

The introduction of a Lewis acid and a chiral ligand makes possible the enantioselective radical cyclization reactions (see **Stereoselective Radical Reactions**). An elegant example reported by Miyabe and coworkers is illustrated in Scheme 15.⁵⁷ In the presence of stoichiometric amounts of Zn(OTf)₂ and a bis(oxazoline) ligand, the Et₃B-initiated reaction of *N*-allyl-*N*-methoxymethacrylamide with excess isopropyl iodide at -78 °C provides the cyclized product in 75% yield with an 82% ee.

While most efforts in iodine ATRC reactions have been devoted to the inhibition of the competing intermolecular radical addition processes, it is interesting to note that the oligomerization

via intermolecular iodine ATRA is also useful in organic synthesis.^{56,58,59} Li and coworkers have demonstrated that, upon heating or treatment with an acid, the oligomeric mixture generated from the intermolecular ATRA reactions of allyl iodoacetate can be deoligomerized to afford 5-(iodomethyl)dihydrofuran-2(3*H*)-one in 92% yield (Scheme 16).⁵⁸ The oligomeric mixture can also be converted cleanly to pent-4-enoic acid on treatment with zinc or to 2,2-diphenyl-5-(hydroxymethyl)tetrahydrofuran by reaction with phenylmagnesium bromide (Scheme 16).⁵⁹ These results have illustrated that radical oligomeric mixtures not only serve as versatile intermediates in organic synthesis but also exhibit unique advantages in that the oligomeric mixtures are self-protected and the deoligomerization functions as the simultaneous deprotection.

4 BROMINE ATOM TRANSFER

Compared to iodine atom transfer, bromine atom transfer reactions are much less investigated, although they are among the earliest examples of ATRAs. This is probably because bromine atom transfer is much slower than the analogous

Scheme 17 Bromine ATRA reactions of α -bromo esters with alkenes.

iodine atom transfer, which makes the undesired radical telomerization competitive in some cases. Nevertheless, bromine atom transfer processes have advantages in that substrate bromides are much cheaper and the products are more stable.

Active bromides such as phenyl tribromomethyl sulfone,⁶⁰ bromomalononitrile,⁶¹ or bromomalonates⁶² readily undergo ATRA reactions with a number of alkenes under direct UV photolysis without the help of an initiator. In the presence of Ni(OAc)₂, borohydride exchange resin (BER) and NaI, the reactions of α -bromo carbonyl compounds with enol ethers in methanol provide the radical addition products as the corresponding acetals, as shown in Scheme 17.⁶³ Further investigation by Curran and Ko has revealed that BER simply functions as a base and the same reactions can be carried out efficiently in the presence of triethylamine under the initiation of AIBN (Scheme 17).⁶⁴ With the initiation of Et₃B/O₂, ATRA reactions of α -bromo carbonyl compounds with mono- or disubstituted alkenes can be accelerated in polar

solvents such as *N,N*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO), or protic solvents such as 2,2,2-trifluoroethanol (TFE) and aqueous media (Scheme 17).⁶⁵ *Ab initio* calculations indicate that a polar solvent tends to lower the relative energies of the transition states. The coordination of a carbonyl group to a proton in a protic solvent, such as a Lewis acid, may also increase the efficiency of the propagation.

Lewis acids also play an important role in bromine atom transfer reactions. For example, very poor conversion (<10%) is observed in the Et₃B/O₂-initiated addition of 3-(bromoacetyl)-2-oxazolidinone to 3-hexene. However, the addition of 1 equiv of Yb(OTf)₃ results in a clean bromine ATRA reaction with 100% conversion (Scheme 18).⁶⁶ Furthermore, control of stereochemistry in the atom transfer addition is possible by the use of chiral auxiliary oxazolidinones. Another example is the radical allylation of β -alkoxy esters using allyltrimethylsilane in the presence of MgBr₂·OEt₂ reported by Guindon *et al.*

Scheme 18 Lewis acid-promoted bromine ATRA reactions.

Scheme 19 Asymmetric bromine ATRC reactions.

(Scheme 18).⁶⁷ The chelation of the substrates to $\text{MgBr}_2 \cdot \text{OEt}_2$ allows excellent control over the diastereoselectivity. Both *syn* and *anti* bromides lead predominantly to the same *anti* product. As a comparison, the analogous *syn* iodide fails to give the allylation product; only hydroxylation occurs.

With the help of a chiral auxiliary, the Lewis acid-catalyzed ATRC reactions of unsaturated α -bromo oxazolidinone imides proceed with an excellent diastereoselectivity (Scheme 19).⁶⁸ The use of chiral Lewis acids allows enantioselective bromine ATRC reactions to occur, even in a catalytic manner.⁶⁹ Yang *et al.* have demonstrated that, in the presence of $\text{Mg}(\text{ClO}_4)_2$ (30 mol%) and a chiral bis(oxazoline) ligand (33 mol%), unsaturated α -bromo β -keto esters undergo 5-exo cyclization reactions to give the ATRC products in good yields with an enantiomeric excess up to 94% (Scheme 19).⁶⁹ These results have clearly illustrated the great potential of atom transfer processes in organic synthesis.

It should be pointed out that a number of ATRC reactions of unsaturated α -bromo esters or amides can be catalyzed by transition metal complexes such as Cu(I) complexes,^{15c} which will be discussed in the next section.

5 CHLORINE ATOM TRANSFER

As discussed in Section 2, the majority of successful chlorine atom transfer reactions require the assistance of transition metal complexes and proceeds via the mechanism shown in Scheme 2. A number of

transition metals have been found to catalyze chlorine atom transfer processes. Among them, copper and ruthenium complexes have received the most attention.

Cuprous chloride has been shown to catalyze the intermolecular addition of polychlorinated compounds to alkenes.^{16,70} Of particular interest is its ability to catalyze the ATRC reactions of allyl trichloroacetates or amides to provide functionalized γ -lactones or lactams.⁷¹ The reactions are typically carried out in acetonitrile at high temperatures (Scheme 20). To improve the catalyst efficiency, a number of ligands have been introduced, including 2,2'-bipyridine (bpy),^{72,73} *N*-alkyl-2-pyridylmethanimines,⁷⁴ multidentate amines or pyridines,⁷⁵ bis(oxazoline),⁷⁶ and even *N*-heterocyclic carbene ligands.⁷⁷ The use of these Cu(I) complexes not only allows the reactions to be performed under milder conditions but also significantly extends the scope of reactions. Less reactive dichloroacetates can now undergo efficient ATRC reactions. For example, the $\text{Cu}(\text{bpy})\text{Cl}$ -catalyzed reaction of pent-4-enyl dichloroacetate in refluxing benzene offers the eight-membered lactone in 92% yield as a mixture of two stereoisomers in 70:30 ratio (Scheme 20).⁷³ The analogous cuprous bromide complexes can be employed to catalyze the cyclization of unsaturated α -bromo amides, as demonstrated by Clark *et al.*⁷⁸ Nevertheless, relatively high catalyst loading is required in these copper-catalyzed transformations. To partially deal with this problem, solid-supported reagents⁷⁹ and perfluorous catalysts⁸⁰ have also been developed to allow the recovery and reuse of catalysts.

Scheme 20 Cu(I)-catalyzed chlorine ATRC reactions.

Scheme 21 Representative ruthenium catalysts for chlorine atom transfer reactions.

Ruthenium complexes have also been shown to catalyze chlorine atom transfer reactions. Among them, $(\text{Ph}_3\text{P})_3\text{RuCl}_2$ is the first Ru(II) catalyst developed for chlorine ATRA^{18,81} and ATRC⁸² reactions of chlorinated compounds to alkenes. Much effort has been made to improve the catalytic activity, leading to the development of a number of ruthenium catalysts of more complex structures, some of which are listed in Scheme 21.^{83–85} However, these Ru(II) complexes display low catalyst stability and consequently show low turnover numbers (TONs) typically.

In order to increase the lifetime of catalyst, Severin *et al.* have nicely demonstrated that the use of $\text{Cp}^*\text{Ru}(\text{PPh}_3)_2\text{Cl}$ or even $\text{Cp}^*\text{Ru}(\text{PPh}_3)\text{Cl}_2$ in the presence of AIBN leads to a dramatic increase in catalyst efficiency.⁸⁶ As illustrated in Scheme 22, when only 0.005 mol% of $\text{Cp}^*\text{Ru}(\text{PPh}_3)_2\text{Cl}$ is used for the reaction of CCl_4 with styrene at 60 °C, a conversion of only 3% is observed after 24 h. Apparently, the high concentration of CCl_4 relative to the catalyst leads to the rapid deactivation of the catalyst by turning the Ru(II) to inactive Ru(III)–Cl. However, in the presence of 5 mol% of AIBN, a complete conversion can be observed with the desired ATRA product in 83% yield (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**). This is because the carbon-centered radical derived from AIBN can regenerate the Ru(II) catalyst by

abstraction of a chlorine atom from Ru(III)–Cl. Switching the Ru(II) complex to the more stable Ru(III) complex $\text{Cp}^*\text{Ru}(\text{PPh}_3)\text{Cl}_2$ also leads to the complete conversion with the mono adduct in 85% yield, which corresponds to a TON of 17 000 for the catalyst. A TON of 44 500 is observed in the $\text{Cp}^*\text{Ru}(\text{PPh}_3)\text{Cl}_2/\text{AIBN}$ -catalyzed reaction of CCl_4 with 1-hexene. In addition to AIBN, magnesium metal can also be used as the reducing agent, allowing the easy separation of the cocatalyst.⁸⁷ More importantly, the reactions can now be performed under milder conditions, resulting in a higher efficiency and better control over stereoselectivity. Further mechanistic studies⁸⁸ have revealed that the $\text{Cp}^*\text{Ru}(\text{PPh}_3)_2\text{Cl}$ - or $\text{Cp}^*\text{Ru}(\text{PPh}_3)\text{Cl}_2$ -catalyzed ATRA reaction is of zero order with respect to chlorinated compounds. This is in contrast to what is observed for less active catalysts such as $(\text{Ph}_3\text{P})_3\text{RuCl}_2$, which show a first-order dependence of the reaction rate on the chlorinated substrate. Furthermore, the kinetic data suggest that the metal catalyst is not directly involved in the rate-limiting step of the reaction. An interesting extension of the above processes is the cyclopropanation of alkenes by a sequential ATRA and dechlorination in the presence of a ruthenium catalyst and magnesium in a one-pot, two-stage manner, as shown in Scheme 22.⁸⁹

Scheme 22 Ruthenium-catalyzed ATRA reactions.

Scheme 23 Copper-catalyzed atom transfer reactions in the presence of AIBN or V-70.

The remarkable effect of AIBN is also observed in copper-catalyzed ATRA reactions of polyhalogenated compounds, as reported by Eckenhoff and Pintauer.⁹⁰ Both Cu(I) and Cu(II) complexes can be utilized as catalysts. Other than AIBN, the free radical initiator 2,2'-azobis(4-methoxy-2,4-dimethyl valeronitrile) (V-70) can also be used in these processes.⁹¹ By taking advantage of the lower decomposition temperature of V-70, the ATRA reactions of polyhalogenated compounds with alkenes can be performed at a lower temperature, enabling selective formation of the mono adduct with highly active monomers such as methyl acrylate or vinyl acetate. The addition of CCl_4 to 1,6-dienes also proceed efficiently by catalysis of only 0.02 mol% of $\text{Cu}(\text{TPMA})\text{Cl}_2$ [tris(2-pyridylmethyl)amine (TPMA)] together with 5 mol% of V-70, furnishing the cyclopentane products in excellent yields (Scheme 23). Kinetic studies by Pintauer *et al.* have shown that in these ATRA reactions the rate of alkene consumption is dependent on the concentration and rate of

decomposition of AIBN, but independent of the concentration of the copper catalyst.⁹² This method is then successfully extended to bromine ATRA and ATRC reactions.⁹³ For example, in the presence of AIBN, the ATRA reactions of CBr_4 or CHBr_3 to alkenes can be successfully carried out via the catalysis of $\text{Cu}(\text{TPMA})\text{Br}$ or $\text{Cu}(\text{TPMA})\text{Br}_2$ of ppm concentrations.⁹³ Similarly, the ATRC reactions of *N*-allyl-2-bromoalkanamides proceed smoothly with the catalysis of only 1 mol% of CuBr/TPMA when 10 mol% of AIBN is also present (Scheme 23). Thus, these recent advances in transition-metal-catalyzed ATRA and ATRC reactions have clearly shown their great potential in industrial applications.

6 PHENYLSELENO GROUP TRANSFER

Like halogen atoms, chalcogens such as selenium and tellurium can also take part in ATRA and ATRC reactions. Among them, the phenylseleno transfer

Scheme 24 ATRA reactions of α -heteroatom-stabilized radicals.

chemistry has been extensively investigated. In general, the transfer of phenylseleno group is of comparable rate to the analogous bromine atom transfer but is much slower than the iodine atom transfer. However, by taking advantage of the greater ionic stability of organoselenium compounds, the phenylseleno group transfer exhibits different behaviors in many cases.

The first examples of phenylseleno group transfer were reported by Byers and Lane.⁹⁴ Here, diethyl phenylselenomalonate undergoes the radical addition reaction with 1-octene upon sunlamp irradiation or heating in the presence of AIBN.^{94,95} Simple phenylselenenyl ketones, esters, nitriles, sulfones, and bisphosphonates can also be employed in these group transfer reactions.⁹⁶ Phenylselenotrichloromethane adds to alkenes upon photolysis, and the products can be converted to α,β -unsaturated carboxylic acids.⁹⁷ More importantly, the stability of α -heteroatom-substituted selenides now enables them to serve as the radical precursors for heteroatom-stabilized radicals. For example, 2-phenylseleno-1,3-dithiane adds to electron-deficient alkenes, while the

captodative radical derived from α -methoxy- α -phenylselenoacetate adds to both electron-deficient and electron-rich alkenes (Scheme 24).⁹⁸ In the meantime, the phenylseleno transfer addition of malonyl or malononitrile radical to heteroatom-substituted alkenes such as enol ethers or enamides readily proceeds to give the stable phenylseleno transfer products, whereas the analogous iodine atom transfer fails.⁹⁹ The addition of phenylselenomalononitriles to 1,2-disubstituted alkenes exhibits good to high stereoselectivity. An excellent diastereoselectivity is achieved in their reactions with (–)-8-phenylmenthol enol ethers (Scheme 25).⁹⁹ Taking advantage of the slow rate of phenylseleno transfer, Renaud and Vionnet have demonstrated that the regioselective radical addition of phenylselenomalonate to 7-oxabicyclo[2,2,1]hept-5-en-2-one is followed by rearrangement prior to phenylseleno transfer (Scheme 25), which serves as the key step for all-cis-Corey lactone synthesis.¹⁰⁰ Ryu *et al.* have shown that the radical addition of phenylselenoacetates to alkenes is followed by the trapping of CO prior to phenylseleno transfer, leading to the

Scheme 25 Phenylseleno transfer to α -heteroatom-substituted radicals.

Scheme 26 Stereoselective ATRC reactions of organoselenides.

isolation of acyl selenides as the three-component condensation products.¹⁰¹

Significant progress has also been achieved in phenylseleno group transfer cyclization. Allyl phenylselenoacetates and *N*-allyl-2- (phenylseleno) acetamides undergo preferably 5-exo cyclization reactions.^{102–104} For example, the cyclization of α -phenylseleno *N*-(2-butenyl)-*N*-methyl-3-oxo-3-phenylpropanamide followed by oxidation with H_2O_2 provides stereoselectively the corresponding γ -butyrolactam, which serves as the key intermediate for the synthesis of ($\pm$)-isocyanometrine (Scheme 26).¹⁰⁴ The cyclization of 5-(4-pentenyl)-5-phenylseleno-1,3-dioxolane-4-one also proceeds stereoselectively, leading to the synthesis of 1-hydroxycyclopentanecarboxylic acid derivatives (Scheme 26).¹⁰⁵ The radical cyclization onto vinyl silyl ethers followed by the cleavage of Si–C bond via tetrabutylammonium fluoride (TBAF) and subsequent β -elimination allows the stereoselective introduction of a vinyl group to the radical center (Scheme 26).¹⁰⁶

Phenylseleno transfer radical cyclization reactions can also be promoted by Lewis acids, allowing the reactions to be performed at a lower temperature with higher regio- and stereoselectivities. The cyclization of unsaturated α -phenylseleno β -hydroxy esters is significantly accelerated by Et_2AlCl and excellent diastereoselectivities are

achieved.¹⁰⁷ The cyclization via 5-exo, 6-endo, or 7-endo mode can thus be successfully implemented, depending on the substitution pattern of the C=C double bonds. In the presence of $\text{Yb}(\text{OTf})_3$ or $\text{Mg}(\text{ClO}_4)_2$, unsaturated α -phenylseleno β -keto amides undergo heteroatom transfer cyclization to give mono- or bicyclic products in a highly efficient regio- and stereoselective manner (Scheme 27).¹⁰⁸ Enantioselective phenylseleno group transfer tandem cyclization can also be designed with the catalysis of chiral Lewis acids, as demonstrated by Yang *et al.* (Scheme 27).¹⁰⁹

7 ARYTELLURO GROUP TRANSFER

Organotellurium compounds exhibit unique characteristics in halogen and chalcogen transfer chemistry.¹¹⁰ In general, the rate of ArTe group transfer is comparable to that of the iodine atom transfer but much faster than that of the PhSe group transfer (see **Sb, Bi, Te, and I-Transfer Polymerization and Applications**). The high rates of aryltelluro group transfer, together with the ionic stability of organotellurides, allow a number of ArTe group transfer processes to take place, whereas the analogous halogen or phenylseleno transfer fails.

Carbotelluration of alkynes proceeds upon photolysis or heating in the presence of AIBN to

Scheme 27 Lewis acid-promoted tandem radical cyclization reactions.

Scheme 28 Carbottelluration of alkynes.

afford the corresponding vinyl tellurides in good yields.¹¹¹ Primary, secondary, and tertiary alkyl and benzyl tellurides are all suitable substrates for the carbottelluration. Alkynes bearing an aryl or electron-withdrawing substituent undergo carbottelluration very efficiently, while alkyl-substituted alkynes give moderate to poor yields of adducts. The stereochemistry is kinetically controlled and mainly affected by steric effect. The competitive reaction of PhTe^iPr and ^iPrI with phenylacetylene indicates that the addition of PhTe^iPr is about 10 times faster than that of ^iPrI , revealing the ease of phenyltelluro transfer. In a similar manner, vinylic *C*-glycosides can also be prepared from the addition of telluroglycosides to alkynes.¹¹² An interesting extension of carbottelluration involves the three-component condensation of trimethylsilyl phenyl telluride, carbonyl compounds, and alkynes, as reported by Yamago and Yoshida.¹¹³ The reaction of silyl telluride with carbonyl compounds proceeds first to give the α -silyloxy tellurides, which then add to alkynes to afford the corresponding silylated allylic alcohols with high *E*-stereoselectivities

(Scheme 28). It should be noted that vinyl tellurides are versatile intermediates in organic synthesis.¹¹⁴ For example, vinyl tellurides prepared by carbottelluration of terminal alkynes followed by oxidation with NaClO and subsequent pyrolysis furnish the internal alkynes in good yields (Scheme 28).¹¹⁵

Carbottelluration of isonitriles has also been proven successful. Organotellurium compounds as precursors for benzyl, α -alkoxy, α -amino radicals add to isonitriles to provide the corresponding imidoylated products.¹¹⁶ For example, telluroglycosides react with isonitriles (see **Unusual Radical Acceptors**) under photothermal conditions to give 1-telluroimidoylglycosides (Scheme 29). Good yields are obtained in the reactions of aromatic isonitriles, whereas the less reactive alkyl-substituted isonitriles give poor yields of products. The three-component condensation of silyltellurides, carbonyl compounds, and isonitriles leads to the formation of α -silyloxy imines, which can be converted to a variety of α -hydroxy carbonyl compounds such as α -hydroxy amides by exploiting the reactive C–Te bond (Scheme 29).

Scheme 29 Carbottelluration of isonitriles.

Scheme 30 Group transfer cyclization of organotellurides.

Intermolecular group transfer addition of organotellurides to alkenes is rare if any presumably because of the lack of sufficient driving force and poor stability of the related organotellurium compounds. However, group transfer cyclization of organotellurides has been demonstrated to be successful by Engman and Gupta.¹¹⁷ For example, β -(allyloxy)alkyl aryl tellurides undergo group transfer 5-exo cyclization to afford substituted tetrahydrofurans upon photolysis with catalytic $(\text{Bu}_3\text{Sn})_2$ (Scheme 30). As a comparison, the analogous selenides fail to undergo group transfer cyclization because of the much lower rate of phenylseleno group transfer.

Acyl tellurides of aryl and vinyl carboxylic acids, which can be readily prepared by the reaction of sodium aryl tellurides with acyl chlorides or mixed anhydrides, are excellent sources of acyl radicals as demonstrated by Crich *et al.*¹¹⁸ Upon photolysis with a simple white light source, acyl tellurides are shown to participate in very efficient group transfer cyclization reactions onto alkenes with the formation of five-, six-, and even eight-membered rings (Scheme 31). Again, the analogous phenylselenenides fail to undergo group transfer cyclization. Acyl tellurides also react with isonitriles to give the corresponding group transfer imidoylation products.¹¹⁹ Carbamottelluroates are shown to

Scheme 31 Cyclizations of acyltellurides.

add to acetylenes to yield β -telluroacrylamides.¹²⁰ When the reactions are carried out intramolecularly, α -alkylidene- β -lactams can be obtained via 4-exo cyclization (Scheme 31).¹²¹

8 CONCLUSION

Atom transfer radical reactions have become an indispensable tool for carbon–carbon bond formations. They provide a powerful, atom-economic, and nonreductive complement to the tin hydride method for conducting radical addition reactions. The halogens or chalcogens are retained in the products, allowing further transformations. The introduction of Lewis acids increases the efficiency and regio- and stereoselectivity in many cases. Enantioselective atom transfer reactions can also be successfully implemented with the help of chiral Lewis acids. Transition metal catalysts, in combination with reducing agents, make the ATRA and ATRC reactions more efficient and environmentally friendly. The rich and versatile atom transfer chemistry should be of increasing importance in organic synthesis in the near future.

Xanthates and Related Derivatives as Radical Precursors

Samir Z. Zard

Laboratoire de Synthèse Organique, Ecole Polytechnique, Palaiseau, France

1 INTRODUCTION

Xanthate salts or (or dithiocarbonates, $R-O-C(=S)-SM$), derived by the simple reaction of an alcoholate with carbon disulfide, were discovered by Zeise nearly two centuries ago.¹ They have found extensive use as flotation agents in the mining industry and in the manufacture of viscose (artificial silk) and cellophane wrapping films.² The thermal fragmentation of xanthate esters to give olefins is called *Chugaev elimination*, a well-known but infrequently applied reaction.^{3,4} An infinitely more powerful transformation involving xanthates was reported in the early 1970s by Barton and McCombie.⁵ It is a radical process that was initially designed to deoxygenate secondary alcohols $R-OH$ through *cleavage of the R-O bond* in the corresponding xanthate $R-O-C(=S)-SMe$ (or, more generally, in compounds of structure $R-O-C(=S)-Z$), but which ultimately emerged as an extremely versatile method for generating carbon radicals that can be incorporated in numerous radical sequences.^{6–11} The Barton–McCombie deoxygenation reaction represents a major advance in the application of radical processes to synthetic problems: spectacular deoxygenations on incredibly complex structures that still cannot be accomplished by known ionic and organometallic methods nearly 40 years later.

More recently, the cleavage of the $R-S$ bond in xanthates of type $R-S-C(=S)-OEt$, and more generally in dithiocarbonyl compounds of gross structure $R-S-C(=S)-Z$, has constituted the basis of

a versatile degenerate radical transfer of xanthates and related groups. Both the Barton–McCombie deoxygenation and the degenerative transfer are discussed in the present chapter.

2 MECHANISM AND SYNTHETIC APPLICATIONS OF THE BARTON–MCCOMBIE DEOXYGENATION

The Barton–McCombie deoxygenation proceeds by the mechanism displayed in Scheme 1, which is a slightly modified version of the one originally proposed by Barton and McCombie. The modification concerns the first propagation step, namely the addition of the tributylstannyl radicals to the thiocarbonyl group of the xanthate, which was found to be fast and reversible.^{12,13} The slow rate-determining step is the irreversible fragmentation of intermediate **2** to give radical $R^\bullet$ and *S*-tributylstannyl dithiocarbonate **3**. Hydrogen abstraction from the stannane is fast and irreversible, furnishing the alkane, RH , and tributylstannyl radicals to propagate the chain. The main driving force is the conversion of a $C-S$ π bond into the much stronger $C-O$ π bond. Stannyl dithiocarbonate **3** may be observed by ^{119}Sn NMR below $-20^\circ C$, but above this temperature it swiftly extrudes carbon oxysulfide to give tributyltin sulfide **4**.¹⁴ Placing a methyl group on the sulfide sulfur of the xanthate disfavors the unwanted scission of the $C-S$ bond in intermediate **2**, for this would lead to a

Scheme 1 Mechanism of the Barton–McCombie deoxygenation.

high-energy methyl radical as well as to stannyl xanthate **5**. Hence, in most structures, the fragmentation proceeds preferentially in the desired direction, on the side of the oxygen. In some cases, side products are observed that are derived either by premature reduction of intermediate **2** by the stannane or, more likely, by further reduction of the thionoformate derived from alkoxythiocarbonyl radical **6**.^{12,13,15–18} Incidentally, it was also demonstrated that radicals **6** can undergo extrusion of carbon oxysulfide to give radicals $\text{R}^\bullet$.^{17,18}

In practice, the Barton–McCombie reaction is best suited for deoxygenating secondary alcohols. Xanthates of tertiary alcohols are usually thermally unstable, decomposing readily into an alkene through the Chugaev elimination, sometimes even below room temperature. The deoxygenation is nevertheless highly efficient in cases where the Chugaev elimination is sufficiently slow at ambient temperature to allow handling of the xanthate.¹⁹ Xanthates derived from bridgehead tertiary alcohols belong to this category. If needed, the chain reaction may be initiated at low temperature using a combination of triethylborane and oxygen for example.²⁰

In the case of primary alcohols, the hurdle is the greater energetic cost of forming a primary carbon radical from intermediate **2**.²¹ The competition

between the expulsion of a primary radical by scission of the C–O bond and a methyl radical by cleavage of the C–S bond is no longer totally biased toward the former mode. The collapse of **2** is a unimolecular step with a large positive entropy of activation; it is therefore highly temperature-sensitive and can be accelerated considerably by operating at higher temperatures. However, this does not obviate the danger of competitive C–S bond cleavage, which is also a unimolecular fragmentation with an equally large positive entropy of activation. In this respect, it is usually advantageous to start with other thiocarbonyl derivatives pictured in Scheme 2, such as thiocarbonyl imidazolides **7**,^{5–11} *O*-arylthionocarbonates **8**,^{22–24} or thionocarbonates,²⁵ where the fragmentation of the intermediate radical adduct corresponding to **2** can occur only on the side of the oxygen. These alternative thiocarbonyl derivatives are also suitable substrates for the deoxygenation and follow the same mechanism (the –SMe group in the xanthate is just a spectator in the addition–fragmentation process outlined in Scheme 1). These precursors are often easier to prepare than xanthates, but are more expensive. As for the xanthates themselves, they are readily obtained by treatment of the requisite alcohol with a strong base, carbon disulfide, and methyl

Scheme 2 Synthesis of precursors for the Barton–McCombie deoxygenation.

iodide, normally in this order (Scheme 2), but variations have been reported where all the ingredients are mixed in the presence of a phase transfer catalyst.^{26,27} A word of caution must be said concerning xanthates **9** derived from allylic (and propargylic) alcohols, which can undergo a relatively easy [3,3]-sigmatropic rearrangement into allylic dithiolcarbonate **10** as indicated in Scheme 2.²⁸

The Barton–McCombie deoxygenation has been applied on more than a thousand natural products and synthetic intermediates, and several reviews have already appeared.^{6–11} An *Organic Reactions* chapter devoted to this transformation, by McCombie, Motherwell, and Tozer, is in press and will soon be published.¹¹ The process is tolerant of many of the functional groups encountered in modern organic synthesis, in line with typical stannane chemistry, and can be applied with success to quite complex structures, even late in a synthetic scheme. Replacing the regular triorganotin hydride with the deuteride or the tritide allows the specific replacement of an alcohol group by a deuterium or a tritium atom. As a consequence of the *reversibility* of the addition of the stannyl radicals to the thiocarbonyl group and the rate-limiting, irreversible fragmentation of intermediate **2** discussed above, it is relatively easy to deoxygenate a secondary alcohol in the presence of a primary alcohol by using a limited amount of stannane.²⁹ In the case of 1,2- and 1,3-diols, selective reductions can be accomplished by use of cyclic thionocarbonates. Bisxanthates derived from 1,2-diols generally lead to alkenes in good yield.^{6–11}

The recent examples listed in Scheme 3 are representative of the unique synthetic potential of the Barton–McCombie deoxygenation. The first two correspond to important steps in the concise total synthesis of (+)-fendleridine and lepadiformine **C** by the groups of Boger and Aubé, respectively.^{30,31} The third transformation (**11** → **12**), taken from Banwell's route to Nobilisinine **A**, showcases the possibility of reducing a xanthate in the presence of a vinylic bromide.³² The use of a thiocarbonyl imidazolide precursor is illustrated by the last step in the synthesis of (±)-*epi*-pumiliotoxin **C** (**13**) reported by Fearnley and Thongsornkleeb.³³ The reduction of lactone **14**, an intermediate in the formal synthesis of (+)-himbacine by Wong and Sherburn, involves the deoxygenation of a thionocarbonate derivative.³⁴

3 TIN-FREE MODIFICATIONS

The considerable difficulty often encountered in removing tin residues and the toxicity of organotin derivatives (see **Tin Hydrides and Functional Group Transformations**), which complicates possible biological testing of the products, has encouraged the development of catalytic systems as well as completely tin-free radical processes. The combination of poly(methylhydrosiloxane) with a small amount of hexabutyltin oxide, reported initially by Grady and Kuivila,³⁵ has been applied to Barton–McCombie type deoxygenations.³⁶ A number of silanes have

Scheme 3 Some examples of Barton–McCombie deoxygenations.

been examined as alternative reducing agents; the most promising are arylsilanes^{37,38} and tris(trimethylsilyl)silane (see **Silanes as Reducing Reagents in Radical Chemistry**).^{39–41} The latter has proven to be especially versatile, even though it is still too expensive to be considered

for large-scale deoxygenations. For instance, tris(trimethylsilyl)silane cleanly reduced xanthate **15**, providing a pure sample of ventricosene **16** (Scheme 4), in contrast to tributylstannane which furnished contaminated material that could not be purified.⁴² Recently, Studer and Walton

Scheme 4 Tin-free Barton–McCombie deoxygenations.

described the use of silylated cyclohexadienes for accomplishing Barton–McCombie deoxygenations under ecologically acceptable conditions.⁴³

As a result of the seminal efforts by Barton and his coworkers,^{44,45} hypophosphorus acid, its salts, and related derivatives have emerged as practical, cheap, and ecologically benign alternative reducing agents to stannanes.^{46–50} The conversion of xanthate **17** into protected lodenosine **18** is not only efficient but could be performed successfully on multikilogram scale.^{51,52} Phosphine–borane complexes^{53,54} and, more recently, *N*-heterocyclic borane complexes have been proposed as hydrogen atom donors for the deoxygenation.^{55–57} Their use has so far been limited, but could increase if specific practical advantages are eventually identified. The same applies for a mechanistically intriguing method

involving a combination of water and a Lewis acid such as boron trifluoride etherate or titanium complexes.^{58,59} A combination of lauroyl peroxide and 2-propanol has also been found to mediate the Barton–McCombie deoxygenation, as illustrated by the reduction of maltose-derived thio-cabonyl imidazolidine **19** into deoxy-maltose heptapi-valate **20**.^{60,61} Incidentally, this method was also applied to the lodenosine problem with equal success.⁶² A more recent and conceptually related procedure involves the use of peroxydisulfate and sodium formate in dimethylformamide (DMF).⁶³ One application pictured in Scheme 4 is the deoxygenation of isopropylidene xanthate **21** to give protected deoxyglucose **22** in high yield. The last two methods are both economical and scaleable.

Scheme 5 Radical cyclizations starting from thionocarbonates.

4 SYNTHETIC VARIATIONS OF THE BARTON–McCOMBIE REACTION

While the Barton–McCombie reaction has mostly been exploited for simple deoxygenations, it represents in fact a very convenient method for generating radicals from alcohols. These radicals can be readily intercepted by internal or, but more rarely, external traps. Two carbohydrate examples of

cyclization, among very many others, are depicted in Scheme 5. Thus, treatment of thionocarbonate **23** with stannane results in the formation of bicyclic product **24** in moderate yield.⁶⁴ The second transformation, taken from work by the same research group, illustrates the trapping of the carbon radical derived from thionocarbonate **25** by an internal oxime to give bicyclic hydroxylamine **26**.⁶⁵ Indeed, the association of the Barton–McCombie reaction with a radical ring closure has proven to be a very convenient and powerful strategy for converting carbohydrates into highly substituted, optically pure carbocycles.⁶⁶

Much less common are instances where the intermediate adduct radical **2** (Scheme 2) is intercepted before the occurrence of the fragmentation step.^{67–71} In a recent study, RajanBabu and co-workers found that the intermediate derived from thiocarbonyl imidazolides may be effectively captured by an internal electrophilic alkene (or even by an oxime), as shown by the reactions presented in Scheme 6.⁷² Interestingly, when compound **27** was treated with *tributyltin* hydride, a modest yield of thiolactone **28** was obtained; in contrast, reaction with *triphenyltin* hydride furnished imidazolidine **29** in good yield. This raises intriguing mechanistic questions, in particular concerning the species that is actually being trapped in each case. For instance, could an alkoxythiocarbonyl radical **6** be involved in the formation of **28**?

Scheme 6 Capture of the intermediate in the Barton–McCombie reaction.

Scheme 7 Neophilic rearrangement of a Barton–McCombie intermediate.

The Barton–McCombie reaction may also be diverted from its normal course by involving intermediate **2** in a neophilic rearrangement (see **Radical Arylations and Radical Rearrangements: Ester-Substituted Radicals and Hydrogen Atom Migrations**). This represents a neat radical-Smiles-based strategy that allows the ultimate replacement of the C–O bond in phenols with a C–C bond. A typical example is reproduced in Scheme 7.⁷³

The Barton–McCombie deoxygenation has been used in a radical modification of the Julia olefination to create alkenes from vicinal hydroxysulfones. The carbon radical resulting from the cleavage of the C–O bond induces the β -fragmentation of the sulfone and expulsion of a sulfonyl radical.^{74–77} One illustrative application is the key step in the total synthesis of tetronasin displayed in Scheme 8.⁷⁷ The elimination produces selectively the desired *E*-alkene.

Practically all the above transformations are in fact in competition with an underlying background reaction, which has not been discussed so far, namely the addition of the intermediate carbon radical to the thiocarbonyl group of the xanthate or related thionocarbonyl precursors. As indicated in Scheme 9, this addition, leading to intermediate **30**, is *reversible* and does not alter the system if it is not followed by the slow but *irreversible* rupture of the C–O bond to give isomeric dithiocarbonate **31**. With most substrates, this radical O $\rightarrow$ S isomerization is too slow under the normal conditions of the Barton–McCombie deoxygenation, and does not therefore interfere. However, when this

Scheme 8 Formation of an alkene by a modification of the Barton–McCombie deoxygenation.

isomerization does indeed take place, it is most often overlooked because dithiocarbonate **31** and starting xanthate **1** have almost identical polarities and cannot be distinguished easily by simple thin-layer chromatography. Since dithiocarbonates **31** are poor substrates for the deoxygenation, the only hint that the isomerization has in fact occurred is the unusually sluggish reduction and the ultimate inordinate excess of reducing agent needed to observe the disappearance of what looks like the “starting material.”

Nevertheless, this radical O $\rightarrow$ S isomerization is of some synthetic interest, for it allows the conversion of alcohols into thiols under very mild conditions. By operating in a concentrated medium *in the absence of a hydrogen atom donor* and by using lauroyl peroxide as the initiator, the isomerization becomes the major pathway, as shown by the conversion of xanthate **32** into dithiocarbonate **33**, with the expected retention of configuration in this case.⁶⁰

A similar reaction can be observed with ketoxime xanthates, where the weakness of the N–O bond facilitates the rearrangement process considerably. The reaction involves the intermediacy of iminyl radicals, which can be captured readily, as shown by the example in the lower part of Scheme 9. Thus, irradiation with visible light of ketoxime

Scheme 9 Radical isomerization of xanthates and generation and capture of iminyl radicals.

xanthate **34** results in the formation of pyrrolenine **36**, through reaction of cyclized radical **35** with the starting xanthate.⁷⁸ Ketoxime xanthates are thermally unstable, and irradiation turns out to be the simplest and most efficient way to trigger the chain process.

5 DEGENERATIVE TRANSFER OF XANTHATES: MECHANISTIC CONSIDERATIONS

A completely different reaction manifold may be obtained by switching the nature of the groups on the starting xanthates so that cleaving the C–S bond becomes the dominant path. A degenerative addition–transfer of the xanthate to an alkene can now be envisaged, as depicted in Scheme 10.^{79–85} Thus, following a chemical or photochemical initiation step, radical $R^\bullet$ arising from rupture of the C–S bond in xanthate **37** is rapidly captured by the starting xanthate to give adduct **38** (path **A**). This radical cannot easily undergo β -scission of the C–O bond, which in

this case would lead to symmetrical dithiocarbonate **39** and a high-energy ethyl radical (Path **B**). Cleavage of the C–S bond is much easier, but only returns the system to its original state, that is, back to $R^\bullet$ and the starting xanthate (Path **C**). The very fast addition–fragmentation is therefore a degenerate process that does not cause any macroscopic change in the system, but the constant regeneration of $R^\bullet$ means that its effective lifetime in the medium is increased dramatically. This “persistence” allows it to participate in various radical transformations, even ones with relatively slow kinetics. For example, addition to an olefin **40** leads to adduct radical **41**; this is followed by a rapid, reversible addition–fragmentation sequence to give finally a new xanthate **43** and radical $R^\bullet$, which can thus propagate the chain. The ethyl on the oxygen atom may be replaced by other groups as long as the corresponding radical is of similar (but preferably of lower) stability as compared to $R^\bullet$. For most applications, a primary substituent is sufficient (methyl, ethyl, neopentyl “*neoPn*,” etc.). *O*-Ethyl xanthates have by far been the most popular, simply

The unique properties and numerous subtleties of the system may be appreciated by examining more carefully the reaction manifold in Scheme 10. There is strong evidence to suggest that adduct radicals such as **38** and **42** are fairly persistent species. Their reaction with radicals of their kind or with other

Some of the far-reaching consequences of these observations are the following: (i) The *absolute* concentrations of the “active” radicals ($R^{\bullet}$ and **41**, and any radicals derived from the initiator) are considerably decreased, causing a very significant diminution in the importance of the termination steps. (ii) It is now possible to operate under very concentrated conditions, not only because the degenerate nature of the reaction of the initial radical $R^{\bullet}$ with its xanthate precursor means that this step does not compete with the desired addition to the olefinic trap **40**, but also because an increase in the concentration favors more the *bimolecular* formation of the “dormant” species in comparison to the *unimolecular* scission leading to the “active” radicals. The process is therefore self-regulating, in terms of keeping the concentration of the “active” radicals low, and thus quite forgiving with respect to modifications in the experimental

setup. (iii) Another consequence is that the *relative* concentrations of all the “active” radicals in the medium are controlled. To a first approximation, and neglecting polar factors, the rate of collapse of the “dormant” intermediates is greater when it leads to more stabilized radicals. Hence, the concentration of the thermodynamically more stable radicals will be higher than that of the less stabilized ones. For instance, a mere 2 kcal mol⁻¹ difference in relative stability between two “active” radicals will result in about 100-fold difference in their relative concentration. So, while the *absolute* steady-state concentrations of all the “active” radicals remain very low, their *relative* concentrations can still differ by several orders of magnitude.

This last property constitutes a key element for controlling the radical addition–transfer process. With the caveat noted above concerning polar factors, the components of the reaction must be selected such that the initial radical R[•] is more “stable” than the adduct radical **41**. In this manner, the fragmentation of the “dormant” intermediate **42** will be biased toward the former, and the steady-state concentration of R[•] will remain much higher than that of radical **41**. The desired addition thus stays favored over the unwanted oligomerization, which occurs by further addition of radical **41** to olefin **40**. Indeed, the greater the difference in stability between R[•] and **41**, the easier it is to control the process. These are crucial factors that have to be kept constantly in mind, especially when dealing with the more challenging *intermolecular* reactions.

There are many advantages, practical and otherwise, attached to the use of the reversible addition–fragmentation of dithiocarbonyl derivatives: (i) The reagents are readily available, cheap, stable, and generally very easy to handle. (ii) The radical additions can be run under high concentrations, typically 1–2 M, and sometimes even without solvent (reduced waste). (iii) The reactions are atom-economical, since all the starting components end up in the product, and highly convergent in the case of the intermolecular variants. (iv) While numerous solvents can be used, including water, the environmentally benign and industrially acceptable ethyl acetate was found to be appropriate for most reactions. (v) No heavy metals are involved. (vi) The processes are self-regulating, safe, and easily scalable. (vii) Although peroxides are usually the preferred initiators for triggering the chain reaction, other initiators such as diazo derivatives, a

combination of triethylborane and oxygen, or irradiation with UV or even visible light, can be used in some cases. (viii) Numerous types of radicals may be directly generated and captured in an inter- or intramolecular fashion; these include not only functionalized alkyl radicals, but also acyl, alkoxy-carbonyl, alkoxythiocarbonyl, nitrogen-centered, and even tin-centered radicals. (ix) The product, being also a xanthate, can act as the starting point for another radical transformation or converted into a myriad derivatives using the exceedingly rich chemistry of sulfur. (x) One final, very important feature is that a classical chain process is not strictly necessary. If the adduct radical **41** (or, more generally, any intermediate radical involved in the actual process in hand) is electron-rich, it can often be oxidized by the peroxide into cation **44**, causing a crossover from a radical to a polar manifold. This oxidation is slow compared to the various radical steps, but it becomes of some importance when dealing with aromatic and heteroaromatic derivatives. In these situations, the peroxide behaves both as an initiator and as an oxidant, and therefore needs to be used in stoichiometric amounts.

6 SOME EXAMPLES OF THE XANTHATE TRANSFER PROCESS

One of the key synthetic features of the xanthate transfer process is its ability to accomplish radical additions to unactivated alkenes and various other typically sluggish radical transformations that are not readily feasible by other methods. The additions of phthalimidomethyl xanthate **45** to various olefins pictured in Scheme 11 are representative.^{86–89} These transformations may be construed as the synthetic equivalent of an aminomethylation process, since reductive removal of the xanthate in the adduct **46** and deprotection would give amine **47**. It is worth pointing out that the phthalimido group exerts a stabilizing effect on intermediate primary radical PhthNCH₂[•], so that the condition for success detailed in point (iii) above is met.

Numerous functional groups are tolerated, both in the xanthate and in the alkene partner, allowing an almost infinite number of possible combinations. Indeed, more than 100 different xanthates have been examined and about 2000 additions performed since the discovery of the reaction in 1988.⁹⁰ Some

Scheme 11 Aminomethylation of alkenes.

Scheme 12 Examples of xanthates that undergo addition to alkenes.

of the synthetically more interesting xanthates are compiled in Scheme 12.^{79–85}

A particularly attractive feature of the system is that the product is also a xanthate, so a second, and sometimes a third, addition can be performed in succession, as long as the initial radical involved is more stabilized than the adduct radical (point (iii) above). This is illustrated by the sequence in Scheme 13, where successive additions to three different alkenes furnish a rather complex protected amine **48**.⁸⁸

Examples concerning the formation and capture of acyl and amidyl radicals are portrayed in Scheme 14. The case of cyclopropylacyl radical **49** is especially interesting, since no decarbonylation or ring opening of the cyclopropyl ring apparently takes place.⁹¹ In the case of nitrogen-centered radicals, only intramolecular reactions have so far been accomplished.⁹²

Ring formation is another area where the xanthate transfer proves useful. In addition to easily formed five-membered rings, it is often possible to construct

Scheme 13 Example of successive additions to three different olefins.

Scheme 14 Examples of generation and capture of cyclopropylacyl and amidyl radicals.

four-, six-, seven-, and even eight-membered rings by direct cyclization. The transformations assembled in Scheme 15 are illustrative. The formation of azetidinone **50** involves ring closure of a carbamoyl

radical, and for these an *S*-acyl dithiocarbamate precursor proved superior to the corresponding xanthate.⁹³ The cyclization leading to piperidinone **51** is a key step in a formal synthesis of lepadin B,⁹⁴

Scheme 15 Examples of formation of four-, six-, and eight-membered rings.

whereas the formation of the eight-membered ring in **52** allows the swift construction of the pleuromutilin skeleton.⁹⁵

The fact that a peroxide may be used both as an initiator and an oxidant, discussed in point (x) above, allows a crossover into a cationic manifold and expands considerably the scope of this technology. The first transformation in Scheme 16 illustrates an ipso reaction on a furan ring, leading ultimately, after further oxidation, to a spirolactone structure **53**.⁹⁶ The second example concerns a difficult 5-*endo* ring closure to give an easily oxidized radical **54**. The final product is a mixture of two isomeric cyclic enamides, which is readily converted into tetracycle **55** possessing the erythrina skeleton.⁹⁷ The lauroyl peroxide in both examples needs to be used in stoichiometric amounts.

More interesting, perhaps, is the possibility of constructing polycyclic aromatic molecules by a direct ring closure on aromatic and heteroaromatic rings. The sequence in Scheme 17 showcases the synthesis of indolines and the multiple uses of chloroacetyl xanthate **56**.⁹⁸ Thus, intermolecular addition followed by cyclization onto the aromatic ring furnishes indoline **57**, which can be readily

converted into a new xanthate **58** by nucleophilic displacement of the chlorine with potassium *O*-ethyl xanthate. This allows a second intermolecular addition, this time to vinyl pivalate, leading to adduct **59**, where the carbon bearing the xanthate and the pivalate groups is in fact a latent aldehyde. Heating this compound with cyclopropylamine in the presence of acid gives rise to pyrrole **60** by a variation on the classical Paal–Knorr synthesis.⁹⁹

The possibility of constructing six-membered rings by direct cyclization onto an aromatic ring may be exploited for the synthesis of tetralones. Two examples are depicted in Scheme 18.¹⁰⁰ The first is a short synthesis of (±)-shinanolone **63**, whereas the second leading to tetralone **64** underscores the complexity that can be rapidly attained and the mildness of the experimental conditions. Two key carbon–carbon bonds are thus created in succession without the epoxide ring being affected. Both these examples are also noteworthy because substrate **61** is a naked phenol. The hydrogen bonding decreases the rate of abstraction of the phenolic hydrogen and freezes the side chain in a conformation that is propitious for ring closure. The result is a significant increase in yield at the cyclization step. Another interesting aspect is that tetralones such as **62** are readily converted into naphthols by simple heating with *p*-TsOH in toluene.¹⁰¹ Indeed, this approach is highly flexible and provides a practical and versatile access to naphthalenes and naphthols with almost any substitution pattern.

Numerous aromatic derivatives to which five-, six-, and sometimes even seven-membered rings are fused can be accessed in a simple, straightforward manner. The same approach can be extended to encompass heteroaromatic structures of interest to medicinal chemists (see Refs 79–85 for a more extensive overview). The case of pyridines is especially important. This heteroaromatic ring is a recalcitrant partner in Friedel–Crafts reactions, and the pool of halogenated and other pyridine derivatives capable of participating in organometallic couplings is comparatively limited in comparison with the benzene series. The xanthate transfer technology is therefore especially attractive since radicals add more readily to the pyridine nucleus than to a benzene ring, and the addition is less reversible. A typical approach providing a 6-azaindoline and a 6-azaindole is outlined in Scheme 20.^{102,103}

Scheme 16 Examples of radical–polar crossover reactions.

In many of these synthesis, the intermolecular addition and the ring closure onto the aromatic can be performed in one pot. With the more reactive heteroaromatic derivatives, such as indoles, the ring closure may in fact be difficult to avoid. An addition–cyclization process was used in a short, formal synthesis of mersicarpine, an alkaloid with an interesting tetracyclic structure (Scheme 19).¹⁰⁴ Because of the presence of the electron-withdrawing ester group, it proved necessary to complete the aromatization process by addition of manganese dioxide. Indole rings are sufficiently reactive to allow *intermolecular* additions to proceed in some cases. The one-step

synthesis of azetidinone derivative **65** is illustrative.¹⁰⁵ Other heteroaromatic rings, such as pyrroles, furans, and thiophenes, may sometimes be cleanly substituted.^{106–108}

One interesting, and quite unusual, transformation involves a radical addition *on the nitrogen atom* of certain pyridine and pyrimidine derivatives.^{109,110} The reaction ultimately leads to pyridones and pyrimidones, once the intermediate adduct radical is oxidized by the peroxide. One such sequence involving a pyrimidine substrate is presented in Scheme 21.¹⁰⁹ New and richly substituted heterocyclic scaffolds such as **66** can thus be cobbled together very simply, for example by selecting

Scheme 17 Synthesis of an indoline by a radical cyclization onto an aromatic ring.

Scheme 18 Synthesis of hydroxytetralones.

Scheme 19 Synthesis of 6-azaindoles and 6-azaindoles.

various xanthate partners from the assortment displayed in Scheme 12.

Some of the examples above have illustrated how the xanthate group in the adduct may be exploited in further radical processes. There are in fact many more radical-based transformations that could be of synthetic interest. The xanthate group may be simply removed by applying any

of the reagents used for the Barton–McCombie deoxygenation.^{79–85} Indeed, because it is the weaker C–S bond that needs to be broken instead of the strong C–O bond, these reductions are invariably faster and more efficient.¹¹¹ The xanthate group may be exchanged with a sulfide,¹¹² a bromine atom,¹¹³ or an azide.^{114–119} New carbon–carbon bonds may be created by exposing the xanthates to various radical traps bearing suitable leaving groups, such as a tributylstannyl,¹²⁰ an alkylsulfone,^{121–126} a diphenylphosphine oxide,¹²⁷ or an epoxide.¹²⁸ In the last case, a combination of triethylborane and oxygen has to be used to mediate the reaction. Four assorted examples are collected in Scheme 22.

The first underscores yet again the potential of xanthates for rapidly building up complexity, since xanthate **67** can initially be added to vinyl pivalate, and the adduct then subjected to an allylation reaction to give skipped enyne **68** in good yield.¹²¹ The second example also uses a sulfone reagent to introduce a dichlorovinyl group on the β -lactam ring.¹²² Compound **69** is thus obtained stereoselectively and in high yield. The use of a phosphine oxide as a prenylating agent is illustrated by the third transformation leading to deoxyglucose derivative

Scheme 20 Reaction of xanthates with indoles.

Scheme 21 Synthesis of dihydro-imidazopyrimidinones.

Scheme 22 Examples of radical allylations and vinylation of xanthates.

Scheme 23 Allyl alcohol derivatives as radical allylating agents.

70.¹²⁷ Finally, the efficient formation of allylic alcohol **71** through the triethylborane/oxygen-mediated addition of a xanthate to a vinyl epoxide highlights the easy creation of a quaternary center on a cyclobutanone.¹²⁸

Except for epoxides, it is generally not easy to cleave homolytically a normal C–O bond. Recently, it was found that the fluoropyridinyloxy group indeed undergoes homolysis of the C–O bond and can therefore act as a leaving group in a radical sense.¹²⁹ Two examples are shown in Scheme 23. The first corresponds to the synthesis of a protected carbohydrate amino acid **73** starting with activated derivative **72**, whereas the second illustrates the formation of a tetrasubstituted alkene **74**. Since the precursor allylic alcohols are themselves usually made by addition of a vinyl metal to a ketone or an aldehyde, the overall process may be construed as a synthetic equivalent of the Wittig olefination. One of the advantages of this approach is that tetra-substituted and otherwise crowded alkenes, such as **74**, that are not easily accessible by a direct Wittig condensation, can be readily obtained by the present addition–elimination of a xanthate.

7 OUTLOOK AND PERSPECTIVES

It is a true wonder that a modest looking functional group such as a xanthate could harbor such a rich and varied radical chemistry. The

Barton–McCombie deoxygenation is still unparalleled in its potency as a method for generating radicals from alcohols. The degenerative xanthate transfer represents a good solution to a long-standing problem in organic synthesis, namely the *intermolecular* formation of carbon–carbon bonds starting with unactivated alkenes. The possibility of iterating the addition of xanthates and related compounds of general structure (RSC(=S)Z) to polymerizable alkenes (monomers) constitutes the basis of the very powerful RAFT-MADIX controlled polymerization technology. This has become a topic of intense research and is discussed in detail elsewhere in this encyclopedia (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**). It is nonetheless worthwhile pointing out that, in addition to the construction of block polymers of almost any architecture, the xanthate transfer can be employed to modify existing polymers. Thus, addition of xanthate **45** to commercial 1,2-polybutadiene **75** shown in Scheme 24 is a representative example; it could in principle be exploited to provide a long-chain polyamine **76** with or without sulfur residues.⁸⁶ The reaction is in practice trivial to conduct, and many functional groups besides amines can be introduced in this manner.

The radical chemistry of xanthates is just a particular case of a broader reaction pattern that can be envisaged for thiocarbonyl derivatives of general formula **77** (Scheme 25). Their reaction with a given radical R[•] (not necessarily carbon-centered)

Scheme 24 Modification of 1,2-polybutadiene.

Scheme 25 General reaction manifold for thiocarbonyl derivatives.

is in principle reversible and leads to a key intermediate **78**. This species can collapse in two ways depending on the nature of X and Y and, to a first approximation (i.e., neglecting polar factors), the relative stabilities of R' and R''. This generic scheme encompasses, for instance, the Barton–McCombie deoxygenation with all the

variations on the precursors, the reversible addition–fragmentation transfer of xanthates and other thiocarbonylthio derivatives (dithioesters, dithiocarbamates, trithiocarbonates), and the Barton decarboxylation involving thiohydroxamic esters (Barton esters). By modifying the substituents in **77**, numerous other useful radical processes can be conceived.

One illustration is the behavior of thiosemicarbazide **79**, which gives intermediate **80** upon radical addition. The comparative weakness of the N–N bond now directs the fragmentation toward the formation of a nitrogen radical. Indeed, thiosemicarbazides and kindred derivatives have emerged as perhaps the best precursors for nitrogen radicals, especially iminyls and amidyls.^{130–133}

Hopefully, the present brief overview will give an idea of the scope and synthetic potential of the radical chemistry associated with xanthates and their relatives. Notwithstanding the variety of transformations described herein, some of which may indeed be viewed as solutions waiting for a problem, this area of research is still in its infancy and much remains to be explored and discovered.

Epoxides in Titanocene-Mediated and -Catalyzed Radical Reactions

Andreas Gansäuer and André Fleckhaus

Kekulé Institut für Organische Chemie und Biochemie der Universität Bonn, Bonn, Germany

1 INTRODUCTION

A promising approach to radical generation is constituted by Lewis acidic activation of and electron transfer to the heterocycle by a low valent metal complex that can potentially act as a catalyst. A first example of an epoxide opening of this type was published by the group of Kochi. They deoxygenated cyclohexene oxide with Cr(II) reagents.¹

In 1988 Nugent and RajanBabu^{2–5} introduced Cp₂Ti(III)Cl as a reagent for epoxide opening through electron transfer. The opening of the epoxide by titanium can be regarded as analogous to the opening of the cyclopropylcarbinyl radical (Scheme 1).^{6–13}

Cp₂Ti(III)Cl is still the most useful reagent for epoxide opening because of its high selectivity and the broad range of consecutive reactions. With titanocene(III) reagents, the typical radical reactions, such as hydrogen atom abstraction,² intermolecular additions to activated olefins,³ and cyclizations of the β -titanoxy radicals formed after ring opening⁴ can be exploited. However, epoxide deoxygenations have also been developed and these reactions are discussed first.

2 EPOXIDE DEOXYGENATION

Usually, epoxide deoxygenations are not highly attractive because epoxides are normally prepared from olefins.

This changes when epoxides are readily available from compounds that are already highly oxidized, such as carbohydrates and their derivatives, or when the resulting olefins are different from the epoxide substrates. The deoxygenation of epoxides was applied in useful transformations of highly functionalized substrates like **1**.

The preparation of **2**⁵ that is rather unstable in 66% yield, which failed by other routes, is remarkable (Scheme 2).¹⁴

Anhydrovinblastine, an important intermediate for the anticancer drug navelbine, was prepared from leurosine, an abundant alkaloid, in 70% yield by using Cp₂TiCl.^{15,16} Stereospecific deoxygenations in the cryptophycin family of natural products from Nostocaceae were also reported.¹⁷

A deoxygenation using enantiomerically pure **3** to give the enantiomerically pure **4** was described (Scheme 3).¹⁸ This approach circumvented Sharpless' kinetic resolution, which implies a maximum yield of 50%.^{19,20}

The competition between radical trapping leading to deoxygenation and mixed disproportionation, a hydrogen atom abstraction on the carbon adjacent to a radical by another radical, has been discussed recently (Scheme 4).²¹

The conversion of 1,3-diepoxydes to 2-ene-1,4-diols has been reported in the context of the synthesis of dihydrotaxoid derivatives.²²

3 REDUCTIVE EPOXIDE OPENING TO ALCOHOLS

3.1 Introductory Remarks

Scheme 1 Synthesis of β -titanoxy radicals from epoxides by the strategy of Nugent and RajanBabu.

So far, $\text{Cp}_2\text{TiCl}^{2,5}$ constitutes the only efficient reagent reported for carrying out this reductive

Scheme 2 Titanocene-mediated deoxygenation of highly functionalized epoxides.

Scheme 3 Deoxygenation of β -hydroxyepoxides leading to enantiomerically pure allylic alcohols.

Scheme 4 Mixed disproportionation of epoxides through hydrogen atom abstraction.

Scheme 5 Mechanism of titanocene-mediated reductive epoxide opening.

epoxide opening. The β -titanoxy radicals were initially reduced by hydrogen atom donors, for example, 1,4-cyclohexadiene or *tert*-butyl thiol. The highly regioselective opening of unsymmetrical epoxides such as **5** (Scheme 5) to give the less substituted alcohols is especially important.

In the case of monosubstituted epoxides up to 33% of deoxygenation and a lower regioselectivity (90:10) in favor of the primary alcohol were observed.⁵ Therefore, the method complements the typical opening of epoxides with hydrides²³ via S_N2 and is much more chemoselective.

3.2 Structure of the Reagent and Mechanism of Ring Opening

Daasbjerg and Skrydstrup have disclosed electrochemical studies on the structure of titanocene(III) reagents in solution.²⁴ It was established that the reduction of Cp_2TiCl_2 with either Mn or Zn leads to the same redox active intermediate. Most likely, the active species in ring opening was not Cp_2TiCl , which is in equilibrium with its dimer²⁵, but the, half-open dimer. Also, the effect of counterions on the reagents' structures was examined.

The transition structures and intermediates were studied by DFT methods.^{26,27} All epoxide openings were exothermic and, in agreement with the experiments, the higher substituted radicals were predicted to be formed preferentially. The regioselectivity of epoxide opening was correctly predicted for the case of propene oxide (9:1). The reasons for the formation of the higher substituted radical are mainly of steric nature because in the early transition structure, the spin density on the developing radical center is low.

3.3 Synthetic Applications

High regioselectivity of ring opening is not confined to unsymmetrical substitution patterns of the epoxide. In 1,2-disubstituted epoxides, excellent results could be therefore observed in many cases,²⁸ for example, exclusive formation of **6** from **1** (Scheme 6).⁵ Most likely, this is also due to steric reasons.

Sharpless epoxides²⁹ and their derivatives are especially valuable substrates in this respect. From these compounds, Nugent and RajanBabu were the first to reduce these radicals to prepare 1,3-diols.⁵ The regioselectivity of epoxide opening was excellent (94:6). Other, more elaborate 1,3-diols could also be obtained.^{30–32} Various 2-methyl-1,3-diol frameworks were synthesized (Scheme 7) and tetrahydrofuran (THF) was proposed as hydrogen donor even though this seems less likely.³³

The ring opening to 1,2-diols was first obtained when the hydroxy group was converted into the trimethylsilyl ether.

Both methods compared very well with the established nucleophilic conditions for regioselective epoxide opening using hydride reagents.³⁴

Also, α,β -epoxy ketones could be opened with Cp_2TiCl in good to excellent yields³⁵ and performed even better than SmI_2 .^{36–43}

Scheme 6 Regioselective opening of 1,2-disubstituted epoxides by RajanBabu and Nugent.

Scheme 7 Regioselective epoxide opening in the formation of 1,3- and 1,2-diols.

3.4 Titanocene-Catalyzed Reductive Epoxide Opening

In general, the use of the titanocenes in catalytic amounts is attractive especially for reagent-controlled radical reactions.^{44–48} The solution of the conceptually similar problem of achieving catalytic turnover^{49,50} in McMurry couplings,⁵¹ Nozaki–Hiyama reactions,^{52,53} and pinacol couplings^{54,55} had been reported by Fürstner and by Hirao by *in situ* silylation of titanium, vanadium, and chromium oxo species with Me_3SiCl . In the case of the epoxide openings, Me_3SiCl was not an

appropriate reagent for the cleavage of a titanium alkoxide because of the high Lewis acidity of silicon that lead to undesired epoxide opening.

Substituted pyridine hydrochlorides^{56–63} emerged as excellent mediators for catalysis. Lutidine and especially collidine hydrochloride performed best in the presence of manganese dust as stoichiometric reductant. The resulting catalytic cycle preserving all attractive features of the stoichiometric reaction is shown in Scheme 8.

The catalytic conditions proved valuable in the enantioselective opening of *meso*-epoxides through electron transfer with preferential cleavage

Scheme 8 Mechanism of the titanocene-catalyzed reductive epoxide opening.

Scheme 9 Enantioselective reductive opening of *meso*-epoxides.

Scheme 10 Regioselective epoxide opening (REO) of 1,2-disubstituted epoxides.

of one of the enantiotopic C–O bonds of the epoxide.^{64–66} Surprisingly, complex **7** possessing the substitution pattern of menthol was as efficient as the phenylmenthol-derived catalyst **8** (Scheme 9).⁶⁷

This concept could be extended to the regiodivergent opening of racemic and enantiomerically enriched epoxides (Scheme 10).^{68,69} In these substrates, the C–O bonds are diastereotopic and can be cleaved with a high degree of catalyst control. The products obtained are interesting for applications in the synthesis of biologically active substances.

3.5 Sustainable Hydrogen Atom Donors

A disadvantage of the reduction of the β -titanoxy radicals by large excesses of 1,4-cyclohexadiene or γ -terpinene is constituted by the generation of stoichiometric amounts of waste, which in the case of benzene is highly toxic.

It has been demonstrated that titanocene(III) reagents activate water and methanol toward hydrogen atom transfer by substantially lowering the bond dissociation energy (BDE) of the OH-bond.^{70,71} Gratifyingly, this most remarkable reagent combination is also chemically more efficient than the

cyclohexadienes and environmentally more benign. Additionally, D₂O can be used to deuterate the radicals formed.⁷² In the presence of collidinium hydrochloride, the reaction can also be performed catalytically in titanocene.

Another attractive hydrogen atom donor is H₂. It has recently been demonstrated that hydrogen atoms can be transferred from classical hydrogenation catalysts to β -titanoxy radicals in a system comprised of two coupled catalytic cycles.^{73,74} It turned out that Wilkinson's catalyst performed very well in this respect, whereas heterogeneous catalysts were not suitable. It remains to be seen if these novel HAT systems can also be employed in enantioselective radical reductions.

4 INTERMOLECULAR ADDITION REACTIONS TO ACTIVATED ALKENES

Epoxide-derived radicals generated under the very mild reaction conditions of titanocene-mediated and -catalyzed electron transfer are excellent intermediates for intermolecular C–C bond forming reactions.^{3,5} The resulting products, δ -hydroxy

Scheme 11 Synthesis of functionalized tungsten carbenes by Merlic *et al.*

Scheme 12 The first use of glycol epoxides as radical precursors by Dötz and Gomes da Silva.

Scheme 13 Intermolecular addition of β -titanoxy radicals onto activated alkenes in the synthesis of thysiferol.

esters, nitriles, amides, and δ -lactones constitute valuable building blocks.

The efficient addition of epoxide-derived radicals to α,β -unsaturated chromium and tungsten carbene complexes as reactive radical acceptors (Scheme 11) highlights the mildness of the conditions.^{75,76}

Extensions of this concept by using sugar-derived carbenes as radical acceptors and by adding radicals derived from the rather sensitive glycol epoxides to α,β -unsaturated carbenes were also investigated

(Scheme 12).⁷⁷ The products obtained are of interest for the synthesis of biologically active substances.

The same system for the addition of carbohydrate-derived radicals was applied with simple organic acceptors with the same selectivities as above.⁷⁸ The same procedure was used in a remarkable approach toward thysiferol (Scheme 13).

The catalytic conditions were well suited for the preparation of δ -hydroxyesters, lactones, and δ -hydroxynitriles.⁶⁰ In this case, alkyl substituted

Scheme 14 Reagent-controlled diastereoselectivity in the addition to acrylates.

titanocenes constituted more efficient catalysts for the often highly diastereoselective addition of radicals to α,β -unsaturated carbonyl compounds (Scheme 14).⁶⁶

The preferential formation of the trans isomers was explained by the shielding of the radicals by the bulky ligands.

Finally, epoxides derived from vinylsilanes have been added to activated olefins, such as acrylonitrile, to obtain synthons for the preparation of functionalized 1,2-diols.⁷⁹

5 TITANOCENE-MEDIATED AND -CATALYZED CYCLIZATIONS

Cyclization reactions,⁸⁰ especially 5-exo cyclizations,⁸¹ have been of outstanding importance to radical chemistry mechanistically and synthetically. Titanocene-mediated and -catalyzed cyclizations have been demonstrated as very attractive in this respect. A schematic mechanism of such cyclizations is depicted in Scheme 15.

Scheme 15 Schematic mechanism of the titanocene-mediated cyclization of unsaturated epoxides.

Scheme 16 3-exo and 4-exo Cyclizations by intramolecular addition to aldehydes and ketones.

5.1 3-exo and 4-exo Cyclizations

The synthesis of small rings via 3-exo and 4-exo cyclizations is considered difficult owing to the high strain of cyclopropanes and cyclobutanes. As a consequence, cyclopropyl- and cyclobutylcarbinyl radicals usually give the ring opening butenyl and pentenyl radicals. With the aid of titanocene complexes, it has been demonstrated in recent years

that this problem can be circumvented by a selective trapping of electrophilic radicals generated through cyclization of nucleophilic radicals.⁸² This has been first exploited in the synthesis of cyclopropanols and cyclobutanols by intramolecular radical addition to aldehydes and ketones as shown in Scheme 16.^{83,84}

Cyclobutanones can be prepared with nitriles as radical traps either stoichiometrically⁸⁵ or catalytically.⁸⁶ Cyclopropanes and cyclobutanes can be

Scheme 17 Titanocene-mediated 5-exo cyclizations.

Scheme 17 (continued)

obtained with α , β -unsaturated carbonyl compounds as radical acceptors.^{82,87–90} Remarkably, even the easily reduced enones are suitable acceptors.

5.2 5-exo Cyclizations

Since the initial report by Nugent and RajanBabu⁴ and the development of the catalytic conditions,^{56–63} many examples of 5-exo cyclization have been reported. The cyclizations are especially powerful in the generation of radicals from highly functionalized epoxides with groups that were typically not tolerated under the conditions of other organometallic

or cationic reactions. Some of the many impressive examples are shown in Scheme 17.^{5,83,85,91–95}

The reaction of epoxy formates with titanocene leads to the synthesis of useful hydroxy lactols.⁹⁶

Titanocene-catalyzed 5-exo cyclizations can be combined with intermolecular addition reactions to tandem sequences for the highly diastereoselective synthesis of tri- and tetrasubstituted olefins.⁹⁷

Finally, first examples of enantioselective 5-exo cyclizations have been reported that rely on the regiodivergent epoxide opening of racemic or enantiomerically enriched Sharpless epoxides (Scheme 18).⁹⁸

Scheme 18 Enantioselective 5-exo cyclizations after regiodivergent epoxide opening of Sharpless epoxides.

Scheme 19 Tetrahydrofuran synthesis featuring homolytic C–O bond cleavage and formation.

5.3 Tandem Sequences Featuring C–O Bond Formation and Cleavage

The titanocene-mediated epoxide opening proceeds with low exothermicity. In the absence of the release of the epoxide ring strain, the cleavage of C–O bonds by titanocenes is endothermic. Thus, the attack of a radical on a Ti(IV)–O bond should result in the formation of a C–O bond and the titanocene(III) reagent. Tandem sequences of this type (Scheme 19) were realized for the synthesis of THFs.^{99,100}

The ring substitution of the titanocene has a marked influence, with electron deficient complexes leading to almost quantitative yields in many cases.¹⁰¹

It should be noted that many furanolignanes were prepared with stoichiometric amounts of Cp_2TiCl in a similar manner.^{102,103} However, it was claimed that iodine had to be added to cleave the Ti–C bonds formed during the course of the reaction. While this seems unlikely to be necessary, the synthetic value of the approach to the lignanes is beyond doubt.

5.4 6-endo Cyclizations and Epoxypolyene Cyclizations

The synthesis of substituted cyclohexanes via 6-endo cyclizations is usually less efficient than the

5-exo cyclization for stereoelectronic reasons. However, with a suitable substitution pattern, the regioselectivity of the addition can be reversed. This is especially interesting for the synthesis of terpenes and for epoxypolyene cyclizations with radicals.¹⁰⁴ It has been demonstrated that the combination of collidine and Me_3SiCl is especially attractive in this sequence. The termination of the cyclizations cascade by a hydrogen atom abstraction that results in the formation of an exo-cyclic olefin in the products makes the radical epoxypolyene cyclization complementary to the cationic reactions where the more substituted olefins are formed during the termination of the sequence. It is therefore not surprising that many natural product syntheses using this protocol have been described.^{105–108} An example is shown in Scheme 20.

An especially important aspect of these reactions is that 7-endo cyclizations can also be included in the tandem sequences.¹⁰⁹ This has resulted in some exceptionally short synthesis of natural products (Scheme 21).

The Coll* Me_3SiCl -mediated catalytic conditions have also been used in transannular cyclizations. The very short semisynthesis of the eudesmanolides from germacranes (Scheme 22) highlights both the power and the mildness of this method in the synthesis of natural products.¹¹⁰

Scheme 20 Epoxypolyene cyclization in the formal synthesis of 8-*epi*-puupehedione.

Scheme 21 7-endo Cyclizations in the synthesis of natural products.

Scheme 22 Titanocene-catalyzed semisynthesis of eudesmanolide from germacrane.

6 SUMMARY AND OUTLOOK

Since the discovery of Cp_2TiCl as a useful reagent for the epoxide opening via ET by Nugent and RajanBabu and the development of the catalytic conditions, many fascinating applications of these protocols have been described and many novel reactions have been developed that unite the advantages of radical chemistry and catalysis. For the future, we expect the use of processes described above in large-scale applications and in the synthesis of ever more complex natural products and, perhaps most importantly, the invention of novel reactions addressing issues of stereoselectivity and sustainability.

Transition Metals and Radicals

Hideki Yorimitsu

Department of Chemistry, Graduate School of Science, Kyoto University, Kyoto, Japan

1 INTRODUCTION

Oxidative addition of an organic halide to a low-valent transition-metal complex is an important elementary reaction in organometallic chemistry. The mechanisms of oxidative addition heavily depend on the type of organic halides. Although oxidative additions of aryl and alkenyl halides occur by concerted pathways, many oxidative additions of alkyl halides occur by radical pathways.^{1,2} However, radical oxidative additions are generally difficult to control because of the high reactivity and short lifetime of the radical intermediates. This difficulty therefore had held back the development of transition-metal-catalyzed reactions of alkyl halides. Recently, the use of alkyl halides as substrates under transition-metal catalysis has been actively investigated.^{3–8} Notably, the investigations have realized intriguing transformations by taking advantage of both radical and transition-metal-catalyzed reactions.

This article begins with two brief summaries about transition-metal-induced Kharasch-type radical reactions and about simple yet intriguing radical initiators, which accompany neither the formation nor cleavage of a carbon–metal bond. The following sections deal with recent studies on sophisticated radical reactions that are well controlled by a transition metal and are hence useful in modern organic synthesis. Radical reactions mediated by samarium diiodide and trivalent titanium complexes are discussed elsewhere (see **Organic Synthesis Using Samarium Diiodide and Epox-**

ides in Titanocene-Mediated and -Catalyzed Radical Reactions). Transition-metal-mediated oxidative radical processes (see **Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry**) and application of transition-metal-controlled radical reactions to polymerization^{9–11} (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications and Fundamentals of Controlled/Living Radical Polymerization**) are presented in other articles of this encyclopedia.

2 TRANSITION-METAL-CATALYZED KHARASCH-TYPE RADICAL REACTIONS

The Kharasch addition reaction, which is the addition of polyhalogenated methanes to alkenes, proceeds in the presence of transition-metal complexes as well as conventional radical initiators such as azobis(isobutyronitrile) (AIBN) and benzoyl peroxide (BPO). Although the transition-metal-mediated additions of polyhalogenated methanes are historically important,^{12–15} they are not really useful from the viewpoint of modern organic synthesis. Inter- and intramolecular radical additions of α -halo carbonyl compounds have attracted more attention in organic synthesis because of the ubiquity and importance of carbonyl compounds. Copper,^{16–18} ruthenium,^{19–21} and palladium^{22,23} salts and/or complexes are frequently employed as mediators. Equations (1)²⁴ and (2)²¹

Figure 1 Transition-metal-mediated chain propagation in atom-transfer radical reaction.

illustrate representative examples of the synthesis of biologically interesting lactone and lactam.

The exact role of the transition-metal complexes in the Kharasch-type atom-transfer radical reactions is still under discussion.²³ Some complexes can simply behave as radical initiators by abstracting a halogen at the initial stage and stay unreactive during chain propagation. Others can serve as a source of halogen via a metal halide in chain propagation, as described in Figure 1.²⁰

3 TRANSITION-METAL COMPLEXES AS CHARACTERISTIC RADICAL INITIATORS

Bis(pentacarbonylmanganese) consists of two pentacarbonylmanganese units connected by a Mn–Mn bond. The Mn–Mn bond is weak enough to undergo homolytic cleavage upon irradiation or heating (see **Overview of Radical Initiation**).^{25–27} The resulting pentacarbonylmanganese radical can abstract iodine atom from alkyl iodides and bromine and chlorine from polyhalogenated alkanes. Advantageously, the byproduct pentacarbonyl-halomanganese is readily removable by using a 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) workup

in purifying the products. Although its rhenium analog behaves similarly,²⁷ it is inferior in terms of the cost and ubiquity. Bis(pentacarbonylmanganese) is effective upon irradiation to induce debrominative homocoupling of allylic bromide (3),²⁸ atom-transfer radical additions (4),²⁹ and deiodinative addition of alkyl iodides to imines (5).^{30–32}

Movassaghi reported that $\text{CoCl}(\text{PPh}_3)_3$ mediates efficient dimerization of benzylic bromides for the elegant synthesis of hexahydropyrroloindole alkaloids (Figure 2).^{33–35} The cobalt complex is much more effective without irradiation than photoactivated hexabutyliditin or bis(pentacarbonylmanganese). The superiority of the cobalt complex would be due to its high reactivity to achieve a high concentration of the corresponding benzylic radical for the dimerization which is of second order with respect to the radical.

4 RECENT RADICAL REACTIONS CONTROLLED BY TRANSITION-METAL COMPLEXES

4.1 Palladium Catalysis

Oxidative additions of alkyl iodides to palladium often proceed by radical processes.³⁶ Suzuki and Miyaura reported that a radical oxidative addition mechanism operates in the palladium-catalyzed cross-coupling reactions of alkyl iodides

Figure 2 Cobalt-mediated efficient dimerization of benzylic bromides for the synthesis of (+)-11,11'-dideoxyverticillin A.

with 9-alkyl-9-borabicyclo[3.3.1]nonanes (9-alkyl-9-BBN).³⁷ Notably, light accelerates the palladium-catalyzed carbonylative cross-coupling (6).^{38,39}

Ryu developed palladium-catalyzed carbonylative cyclization reactions of 5-iodo-1-pentene derivatives under UV irradiation (Figure 3).^{40,41} The reactions provide a variety of (2-oxocyclopentyl)acetates in good yields. They proposed a *radical/palladium hybrid* mechanism. Initial iodine abstraction would take place with the aid of zero-valent palladium under irradiation. Radical carbonylation followed by intramolecular cyclization would afford a 2-oxocyclopentylmethyl radical. Another radical carbonylation would yield the corresponding acyl radical, which would be trapped by palladium(I) iodide to form an acylpalladium intermediate. The reaction of alcohol with the acylpalladium should furnish the product. The intermediary radicals are supposed to be in equilibrium with the corresponding organopalladium species by reversible formation/cleavage of carbon–palladium bonds. The same group^{42–44} and Bloome and Alexanian⁴⁵ also developed several carbonylation

reactions of alkyl iodides based on the concept of the radical/palladium hybrid (7 and 8).

Knochel reported that palladium complexes catalyze the cyclization of 6-iodo-1-hexene derivatives in the presence of diethylzinc to afford cyclopentylmethylzinc iodides (9).⁴⁶ The resulting zinc reagents can react with a variety of electrophiles such as activated organic halides and Michael acceptors after transmetalation with CuCN·2LiCl. The reaction mechanism should include oxidative addition by a radical process to generate cyclopentylmethylpalladium and the following transmetalation with diethylzinc.

Figure 3 Radical/palladium hybrid for efficient carbonylative cyclization.

involvement of a radical oxidative addition process. Cárdenas also reported similar nickel-catalyzed radical cyclization/cross-coupling reactions of 6-iodo-1-hexene derivatives with alkylzinc reagents.⁵²

4.2 Nickel Catalysis

Nickel catalysis is used more frequently than palladium catalysis in the cross-coupling reactions of alkyl halides.^{47,48} Oxidative addition to nickel is believed to proceed by radical mechanisms in most cases.

Fu reported nickel-catalyzed reactions of alkyl bromides with organosilicon⁴⁹ or organoboron⁵⁰ reagents. The cross-coupling reactions of both *exo*- and *endo*-2-bromonorbornane afforded the corresponding *exo* coupling products exclusively (10), which suggests that the reactions would proceed via the same radical intermediate, 2-norbornyl radical, bearing no original stereochemical information. Arylative cyclization of 6-bromo-4-oxa-1-hexene derivatives with trichlorophenyltin⁵¹ or phenylboronic acid⁵⁰ (11) also strongly supports the

Fu subsequently presented asymmetric nickel-catalyzed cross-coupling reactions of racemic secondary alkyl halides (12).^{53–57} The asymmetric transformations proceed with stereoconvergence, which indicates the generation of planar radical intermediates from both enantiomers.

Hirano and Miura found nickel-catalyzed direct alkylation of benzothiazole with alkyl bromides albeit with moderate efficiency (13).⁵⁸ They proposed a radical oxidative addition mechanism since cyclopentylmethylation and 3-butenylation

took place upon treatment with 6-bromo-1-hexene and cyclopropylmethyl bromide, respectively.

In most cases, pyridine-based ligands are efficient for the nickel-catalyzed reactions. Vicic investigated the role of terpyridine as the ligand to elegantly reveal that a (terpyridine)nickel(0) complex does not react with organic halides by oxidative addition (Figure 4).^{59,60} Instead, a (terpyridine)Ni(I)R complex should be generated by a comproportionation reaction between a (terpyridine)Ni(II)R₂ complex and the (terpyridine)nickel(0) complex, and would be responsible for oxidative addition. The (terpyridine)Ni(I)R complex can be best described as a nickel(II)R cation bound to the radical anion of terpyridine. The single unpaired electron is localized mostly on the ligand, and the (terpyridine)Ni(I)R complex effects single-electron transfer

Figure 4 Ni(I)/Ni(III) catalytic cycle for alkyl-alkyl Negishi coupling.

from the ligand to alkyl halide RX to realize a radical oxidative addition mechanism. The catalytic cycle is hence concluded to be a $Ni(I)/Ni(III)$ cycle. Phillips performed density functional theory calculations to provide further evidence for Vicic's mechanism, showing the conventional two-electron oxidative addition is energetically unfavorable.⁶¹ Cárdenas also supported Vicic's mechanism on experimental as well as theoretical basis.⁵²

4.3 Cobalt Catalysis

In 2001, Oshima reported cobalt-catalyzed tandem radical cyclization/cross-coupling arylation reactions of 6-halo-1-hexene derivatives with aryl Grignard reagents (14),^{62,63} which represent the breakthrough in the recent rapid development of transition-metal-controlled radical reactions in organic synthesis. A possible mechanism is illustrated as Figure 5. The reaction of $CoCl_2(dppe)$ with 4 equiv of $PhMgBr$ would afford a zero-valent cobaltate $[Co(0)Ph_2(dppe)](MgBr)_2$ with concomitant formation of biphenyl. The electron-rich ate complex would be responsible for single-electron transfer to a substrate to realize oxidative addition by a radical mechanism. It is fundamental knowledge that oxidative addition of organic halide to

metal can proceed by a radical mechanism.^{1,2} However, little attention had been paid to its application to organic synthesis. This cobalt-catalyzed reaction had shed light on the importance of radical species in cross-coupling reactions of alkyl halides.⁶⁴

(14)

Cobalt catalysis also allows cross-coupling allylation and benzylation of alkyl halides.^{65,66} Notably, tertiary alkyl bromides as well as primary and secondary ones can participate in the allylation, which was not possible by using palladium and nickel catalysis (15). Tandem radical cyclization/allylation justifies the intermediacy of radical species (16). A cobalt (–)-chiraphos complex can catalyze enantioselective allylation of a racemic tertiary alkyl bromide (17). Although the enantioselectivity was very low, the reaction is important as the first trial for the transition-metal-catalyzed enantioselective cross-coupling of racemic alkyl halides, which Fu had been actively developing.^{53–57}

Figure 5 Plausible mechanism of cobalt-catalyzed arylation cyclization.

The scope of the arylation catalyzed by the cobalt–diphosphine complexes is limited to primary alkyl halides.^{62,63} Later, *N,N,N',N'*-tetramethyl-1,2-cyclohexanediamine (TMCHDA) was found to be a superior ligand for cobalt, realizing the use of secondary alkyl halides as coupling partners.⁶⁷ The arylation is highly efficient to go to completion within 15 minutes at room temperature. The intermediacy of planar carbon-centered radicals allows diastereoselective phenylation of chiral bromo acetals, which leads to a variety of phenylated tetrahydrofuran (THF) derivatives

(Figure 6). Combined with a radical cyclization reaction, the cobalt-catalyzed arylation provides an efficient access to a synthetic prostaglandin AH13205 (Figure 7).

N,N,N',N'-Tetramethylethylenediamine (TMEDA) is a suitable solvent for cobalt-catalyzed cross-coupling reactions of alkyl halides with 1-trimethylsilyl-2-ethynyl and trimethylsilyl-2-ethynyl Grignard reagents (18 and 19).⁶⁸

N-Heterocyclic carbene ligands are effective in cobalt-catalyzed sequential cyclization/cross-coupling reactions of 6-halo-1-hexene derivatives with 1-alkynyl and trialkylsilylmethyl Grignard reagents (20 and 21), in which bidentate diphosphine and diamine ligands were completely ineffective.^{69,70}

Figure 6 Cobalt-catalyzed phenylation of chiral bromo acetal.

Figure 7 Synthesis of AH13205.

The major limitation of the conventional Mizoroki–Heck reaction is that one cannot use alkyl halides as substrates mainly because the alkylpalladium intermediates suffer from β -hydride elimination, which always dominates over the insertion of alkene. A combination of $\text{CoCl}_2(\text{dppe})$ ($\text{dppe} = 1,1'$ -

6-bis(diphenylphosphino)hexane) and trimethylsilylmethylmagnesium chloride offers a complementary method that allows the alkylation of styrenes.^{71,72} Primary, secondary, and tertiary alkyl halides all participate in the alkylation (22). Notably, less reactive alkyl chlorides are also good alkyl sources. The use of trimethylsilylmethylmagnesium chloride is quite important, and other Grignard reagents are completely ineffective. In addition, the Grignard reagent has modest reactivity, thereby allowing various functionalities such as ester to survive (23). A catalytic cycle should begin with single-electron transfer to alkyl halide. Radical addition of the resulting alkyl radical to styrene would yield the corresponding benzylic radical (Figure 8). A cobalt complex captures the benzylic radical, and the resulting benzylic cobalt undergoes β -hydride elimination to afford alkylated styrene. Investigation by using typical radical clocks supports the intermediacy of radical species (24 and 25). The cobalt-catalyzed system is also applicable to intramolecular reactions (26).^{72,73}

Figure 8 Catalytic cycle of cobalt-catalyzed alkylation of styrene.

Cobalt-catalyzed Mizoroki–Heck-type reactions of epoxides with styrene take place under similar reaction conditions (27).⁷⁴ Magnesium

bromide-mediated ring-opening of epoxides would afford the corresponding magnesium 2-bromoalkoxides, which are the actual substrates for the reaction.

Conjugated 1,3-dienes are good radical acceptors. Treatment of 1,3-dienes under similar cobalt-catalyzed conditions does not yield the Mizoroki–Heck-type product but results in three-component coupling to afford homoallylic silanes (Figure 9).⁷⁵ Reductive elimination from the allylic cobalt species dominates over β -hydride elimination. Chromium⁷⁶ and nickel⁷⁷ were reported to catalyze similar three-component coupling reactions of 1,3-dienes as radical acceptors.

A combination of a cobalt/IMes catalyst and dimethylphenylsilylmethylmagnesium chloride promotes highly regioselective dehydrohalogenation of alkyl halides (28).⁷⁸ The elimination reaction consists of oxidative addition by a radical mechanism and the following β -hydride elimination from the corresponding alkylcobalt intermediate. The reaction mechanism offers intriguing regioselectivity. For instance, 1-iodo-2-phenylcyclohexane is not converted to conjugated 1-phenylcyclohexene but to unconjugated 3-phenylcyclohexene (29).

Figure 9 Three-component coupling of alkyl halide, 1,3-diene, and trimethylsilylmethyl Grignard reagent.

4.4 Iron Catalysis

Iron is cheap, ubiquitous, and environmentally benign, and hence is an ideal transition metal for catalysis. Like cobalt, iron has been attracting increasing attention in the cross-coupling reactions of alkyl halides.

Oshima developed iron-catalyzed reductive radical cyclization of 6-halo-1-hexene derivatives with phenylmagnesium bromide (30),⁷⁹ wherein single-electron transfer from electron-rich iron-ate species occurs to initiate the radical cyclization and no phenylation takes place.

Nakamura *et al.*,⁸⁰ Nagano and Hayashi,⁸¹ and Martin and Fürstner⁸² independently reported in 2004 iron-catalyzed Kumada–Tamao–Corriu coupling arylation of primary and secondary alkyl

halides (31)⁸⁰ and (32).⁸³ Following these results, a number of reports on iron-catalyzed cross-coupling reactions of alkyl halides with organometallic reagents have appeared, which are summarized in excellent reviews^{5,84–86} and have been extensively cited in a very recent paper.⁸⁷ In most cases, aryl and alkenyl metal reagents are available for use.

The exact reaction mechanism of the iron-catalyzed cross-coupling reactions of alkyl halides is not clear. However, there is sufficient data to suggest oxidative addition by single-electron transfer from electron-rich iron complexes. Like the cobalt-catalyzed processes, strong support of the radical oxidative addition is the loss of the initial stereochemistry of a chiral halogenated carbon (33)^{82,83,88} as well as the following typical radical clock reactions (34).^{82,83,88–92} A representative, plausible mechanism proposed by Nakamura and Nagashima is shown in Figure 10.⁹³

Figure 10 A proposed catalytic cycle for iron-catalyzed cross-coupling.

(33)

(34)

Yoshikai and Nakamura developed iron-catalyzed arylation of *N*-(2-iodobenzyl)-substituted aliphatic amines at the α position with organomagnesium or

organozinc reagents (Figure 11).⁹⁴ They proposed that the reaction mechanism involves the generation of the corresponding aryl radical, which then undergoes 1,5-hydrogen transfer to afford an α -aminoalkyl radical.

Charette reported iron-catalyzed direct arylation of benzene with aryl iodides in the presence of potassium *t*-butoxide (35).⁹⁵ A large amount of benzene solvent is essential to achieve the reaction. A plausible mechanistic pathway involves the formation of an aryl radical from aryl iodide by single-electron transfer followed by intermolecular radical addition to benzene (see **Intramolecular Homolytic Substitutions in Synthesis**). It

Figure 11 Iron-catalyzed arylation at α position of aliphatic amines protected by 2-iodobenzyl group.

should be pointed out that different groups have reported alkali *t*-butoxide-mediated direct arylation of benzene with aryl iodides in the absence of any transition-metal catalysts.^{96–98}

4.5 Silver Catalysis

Silver catalysis has proved to be more robust than the cobalt catalysis^{65,66} for benzylation and allylation of alkyl halides.^{99–101} The reaction procedure is quite simple: a Grignard reagent is added to a mixture of alkyl bromide and a catalytic amount of silver nitrate in ether at room temperature (36). A radical clock experiment as well as stereoconvergent benzylation reactions of *exo*- and *endo*-2-bromonorbornane verify the intermediacy of carbon-centered radicals. Intriguingly, *gem*-dibromoalkanes undergo sequential carbon–carbon bond formation with two different Grignard reagents to create a chiral quaternary carbon center (37). Allylic and benzylic zinc reagents of milder reactivity are also effective under similar conditions (38). Indenyllithium reacts under silver catalysis to yield sterically crowded alkylated indene derivatives.¹⁰² Aryl Grignard reagents can couple with secondary and tertiary alkyl bromides albeit with low efficiency.¹⁰³ Mechanistically, low-valent silver-ate complexes are proposed to be responsible for oxidative addition by a radical mechanism.

4.6 Manganese-Mediated Processes

Activated manganese metal can transfer one electron to alkyl halides. Takai developed three-component coupling of alkyl iodides, electron-deficient alkenes, and carbonyl compounds by using manganese powder activated by catalytic amounts of PbCl₂ and chlorotrimethylsilane (39).¹⁰⁴ Sequential 1,4-addition/Ireland–Claisen rearrangement is also promoted under similar conditions (40).¹⁰⁵ Reduction of alkyl iodide with manganese would generate the corresponding alkyl radical, which then undergoes radical addition to electron-deficient alkene. The adduct would accept another electron to form a stable carbanion, which is responsible for the Aldol-type reaction or the rearrangement.

Manganese-ate complexes are efficient electron donors that promote radical cyclization of 6-halo-1-hexene derivatives (41).^{106–108} Highly active manganese powder, prepared from Li₂MnCl₄ and magnesium, can also promote similar transformations.^{109,110}

4.7 Titanium Catalysis

Styrenes react with alkyl halides in the presence of butylmagnesium chloride and a catalytic amount of titanocene dichloride to afford Mizoroki–Heck-type products (42).¹¹¹ The mechanism would be similar to the cobalt-catalyzed reaction.^{71,72} The functional group compatibility is unsatisfactory because of the high reactivity of the Grignard reagent.

Figure 12 Proposed mechanism of titanocene-catalyzed double alkylation of styrene.

When alkyl bromides having a heteroatom at the β -position are subjected to the titanocene-catalyzed reaction, regioselective double alkylation of styrene takes place (43).¹¹² Mechanistic experiments have revealed the reaction pathway, as shown in Figure 12. Cp_2TiCl_2 would be reduced with alkyl Grignard reagent to generate dialkyltitanate(III) $\text{Cp}_2\text{TiR}_2(\text{MgCl})$. Oxidation of the titanate by β -bromoethyl ether leads to extrusion of alkyl radical $\text{R}^\bullet$. Addition to styrene followed by the capture by a titanocene complex affords the corresponding benzyl titanocene. Subsequent transmetalation with the alkyl Grignard reagent would afford the benzylic Grignard reagent, which finally reacts with β -bromoethyl ether to form the product.

4.8 Zirconium-Mediated Processes

Schwartz reagent is a promising alternative to tributyltin hydride in radical reaction (44).^{113,114} Alkyl chlorides as well as iodides and bromides are reduced smoothly in the presence of triethylborane. Reduction of aryl iodide is also very efficient. Functional groups such as ether and ester can survive under the reaction conditions. Schwartz reagent can be generated *in situ* from zirconocene dichloride by means of an aluminum hydride reagent Red-Al. The amount of zirconocene dichloride can be reduced to catalytic levels.

Allylic zirconocenes are effective for radical allylation of α -halo carbonyl compounds and tandem radical addition/allylation of acrylate esters with alkyl iodides, serving as allyltin surrogates ((45), Figure 13).¹¹⁵

Figure 13 Tandem radical addition/allylation with allylic zirconocene.

(45)

Negishi reagent, a zirconocene(II)-alkene complex, serves as a single-electron transfer agent to induce radical reactions (46).^{114,116,117} In most cases, the Negishi reagent serves as a reducing agent like samarium diiodide. Radical propagation would not operate, and a plausible hydrogen donor is THF.

(46)

5 CONCLUSION

The elementary radical reactions are limited in number and complexity. Combinations of radical reactions with transition-metal-catalyzed ones have provided a wider variety of transformations than

with independent use of standard radical or catalytic technology. Such combinations will continue to significantly expand the scope of radical reactions in organic synthesis.

Radicals and Carbohydrates

Inés Pérez-Martín and Ernesto Suárez

Instituto de Productos Naturales y Agrobiología del C.S.I.C., La Laguna, Tenerife, Spain

1 INTRODUCTION

Radical reactions in carbohydrate chemistry have been a matter of intense research activity during the last years. These synthetic and mechanistic studies have not only decisively contributed to a better understanding of radical reactions but have also played a major role in the transference of these methodologies to the synthetic chemistry community. Of particular note is the contribution of carbohydrate chemistry in evaluating the importance of steric, stereoelectronic, and conformational effects on the reactivity and stereoselectivity of radical reactions. One important aspect of free-radical chemistry at the anomeric center is the predictable stereoselectivity of hexopyranosyl radicals, which makes them valuable intermediates for the stereoselective synthesis of C-glycosides and C-disaccharides.

The application of radical methods in carbohydrate chemistry has been thoroughly reviewed covering the literature up to 1999.¹ Since then, a number of reviews, dealing with specific areas, have been published.^{2–7} Although some earlier work is mentioned, this article reviews progress in the area with special attention to new developments published during the past decade. Because of the great number of publications in this field, an exhaustive review of the literature is not possible. However, an attempt has been made to highlight the most synthetically valuable processes. The major focus is on inter- and intramolecular carbon–carbon bond-forming radical

reactions, with emphasis placed on the preparation of C-glycosides, C-ketosides, C-disaccharides, and branched-chain sugars, as well as on the synthesis of polyfunctionalized carbocycles by radical cyclization of acyclic carbohydrate derivatives. The next two sections describe methods for the formation of carbon–hydrogen bonds and synthesis in which a heteroatom-centered radical plays a clear role in the carbon–heteroatom bond formation. Finally, a few selected examples of alkoxyl radical β -fragmentation reactions, carried out under oxidative or reductive conditions, are included to illustrate their potential in the synthesis of chiral synthons.

2 INTERMOLECULAR CARBON–CARBON BOND-FORMING PROCESSES

Free-radical chemistry at the anomeric center has attracted a great deal of attention owing to the unusual diastereoselectivity (see **Stereoselective Radical Reactions**) of glycopyranosyl radical reactions. These radicals react with electrophilic acceptors to give axial-substituted adducts preferentially, in contrast to cyclohexyl radicals which react principally in the equatorial mode.^{8,9} The reactivity strongly depends on two main stereoelectronic stabilizing effects: the anomeric effect (interaction between the singly occupied molecular p orbital (SOMO) and the adjacent highest occupied molecular orbital (HOMO) of the pyran oxygen lone pair) and the β -oxygen effect

Figure 1 Stereoelectronic effects and conformation of glycosyl radicals. The preferred addition to acrylonitrile is shown by arrows.

(interaction between the SOMO and the σ^* -lowest unoccupied molecular orbital (LUMO) of the coplanar β -C–OR bond).¹⁰ A combination of both effects, the so-called quasi-homo-anomeric effect, has been used by Giese to explain the stereoselectivity of a variety of carbohydrate radical reactions (Figure 1).^{11–13} This quasi-homo-anomeric effect may also induce conformational changes in the glycopyranosyl radical with respect to the original carbohydrate in order to maximize orbital interactions. For instance, the electron paramagnetic resonance (EPR) (see **Analysis of Radicals by EPR**) data for D-glucopyranosyl and D-galactopyranosyl radicals have been interpreted by Giese in terms of a slightly twisted $B_{2,5}$ boat and a 4H half-chair conformations, respectively, instead of the original 4C_1 shape of D-glucose and D-galactose.¹⁴ In contrast, the D-mannopyranosyl radical remains in the 4C_1 chair conformation of the D-mannose. As the configuration at C-2–C-4 in xylose and lyxose is identical to those of glucose and mannose, respectively, similar conformations for D-xylopyranosyl ($B_{2,5}$) and D-lyxopyranosyl (1C_4) radicals were observed by EPR.¹² The much more flexible D-arabinopyranosyl radical exists as an equilibrium between the 4C_1 and $B_{0,3}$ conformation, and their reactions with alkenes are

unselective. However, D-arabinofuranosyl radicals adopt a 2E conformation and react with high diastereoselectivity. The diastereoselective ratios and preferential acrylonitrile attack on the anomeric radicals maintaining the stabilizing interaction with the lone pair of the ring oxygen are shown in Figure 1.^{15,16}

2.1 Synthesis of C-Glycosides

Since its introduction by Keck and Yates¹⁷ in 1982, allyltributylstannane has frequently been used for the synthesis of C-glycosyl compounds. The radical chain reaction (see **The History of Free Radical Chemistry**) is initiated by thermolysis of azobisisobutyronitrile (AIBN) or irradiation, and the mechanism is depicted in Figure 2. The glycosyl radical **I** is generated from the precursor by X (halide, xanthate, thioether, or selenide) abstraction of the stannyl radical. The formed adduct radical **II** undergoes a rapid β -fragmentation of the C–Sn bond to give the allylated compound and the chain propagation tin radical **III**.¹⁸

The reaction has been applied to pyranose,^{19–22} furanose **1**,^{19,23} and N-acetylneuraminic acid **2** derivatives^{24–26} (Scheme 1). As a consequence

Figure 2 Radical chain reaction mechanism of Keck allylation. X: halide, xanthate, thioether, or selenide.

of the α -axial quenching of D-glycopyranosyl radicals,^{10,14} 3-C-(α -D-glycopyranosyl)-1-propene derivatives are formed predominantly. Notwithstanding, the presence of a bulky substituent at C-2 (*N*-phthalimido,²¹ *N*-tetrachlorophthalimido **3**²²) reverses the stereochemical outcome to form β -C-glycosides **4**. A novel approach to the synthesis of 3-C-(β -D-glycopyranosyl)-1-propene derivatives has been reported by Praly *et al.*²⁷ in a one-pot, two-step sequence involving allylation and reductive dehalogenation of 1-bromo- β -D-glycopyranosyl chloride **5**. The reaction may be effected even with electrophilic glycosyl radicals; α -D-arabino-hexopyranosyl-2-ulose bromide **6** reacts with methyl 2-(tributylstannylmethyl)acrylate albeit in moderate yield.²⁸ A study of the conformation–anomeric effect–stereoselectivity relationship in the anomeric radical reaction of pentopyranoses has been reported. Selectivity was increased by conformational restriction of the pentopyranose ring in 4C_1 -chair **7** and completely inverted by flipping the conformation from the 4C_1 - into the 1C_4 -chair **8**, because of the kinetic anomeric effect.²⁹ Allylthio compounds are also effective anomeric radical-trapping agents for the synthesis of C-allyl glycosides. Thus, the ultraviolet (UV) irradiation of α -D-galactopyranosyl bromide with allylic sulfides and sulfones in the presence of hexabutyltin gave the corresponding 3-C-(α -D-galactopyranosyl)-1-propene derivatives with excellent diastereoselectivity.³⁰

D-Gluco-1-yl radicals can also be generated by reaction of D-glucosyl iodide **9** with 1-ethylpiperidine hypophosphite (EHPH) (Scheme 2).

The anomeric radicals add efficiently to pentafluorophenyl acrylate as electron-deficient olefin to give C-glycoside **10**.³¹ EPHP is a mild alternative to tin reagents in radical chemistry. The chemoselective radical reduction of the iodine atom in a series of 1-deoxy-1-halo-1-iodo-alditols and the addition of the intermediate radicals to acrylonitrile has been described.³² One-carbon extended C-glycosylation to glycopyranosides **13** can be achieved by radical acylation of peracetylated gluco- and galacto-pyranosyl bromide **11** with phenylsulfonyl oxime ether **12** in the presence of hexamethyldiastannane under photochemically initiated conditions.³³ The reaction may also be applicable to the preparation of C-branched sugars (see **71** in Scheme 8). In the addition of L-fucosyl radical to α,β -unsaturated ester **14**, two 1,3-distant stereocenters are created with high diastereoselectivity: the first one results from a totally selective α -C-glycosylation under stereoelectronic control and the second by a hydrogen-atom transfer (HAT) reaction which proceeded preferentially to the 2,3-syn isomer **15**.³⁴ Some limitations associated with the use of glycosyl bromides of 2-amido sugar as radical precursors, which in some cases led only to the corresponding oxazoline, prompted Gallagher^{35,36} to examine alternative radical precursors in these compounds. The anomeric selenides derived from D-GlcNAc, D-ManNAc, and D-GalNAc **16** underwent smooth C–Se homolysis and the resulting radicals were trapped with electron-deficient olefins to give C-glycosides **17**. Since the pioneering work on the synthesis of showdomycin by Barton in 1990,³⁷

Scheme 1 Synthesis of C-allyl glycosides by intermolecular trapping of glycosyl radicals with allylstannanes.

some attention has been paid to the preparation of glycosyl tellurides as a source of 1-glycosyl radicals. Yamago and Yoshida³⁸ have shown that anomeric radicals generated photochemically or thermally from glycosyl tellurides such as **18**

add to alkynes to give vinyl C-glycosides **19** in good yield as a mixture of anomers (α/β , 75:25) (see **Halogen and Chalcogen Transfer Chemistry and Sb, Bi, Te, and I-Transfer Polymerization and Applications**). Interestingly, under

Scheme 2 Synthesis of C-glycosides by intermolecular addition of glycosyl radicals to unsaturated compounds. EPHP, 1-ethylpiperidine hypophosphite.

these conditions the reactivity of electron-deficient and electron-rich alkynes is similar, which is surprising given that glycosyl radicals behave as nucleophilic species. This Japanese group also studied the imidoxylation of these organotellurium compounds with isonitriles; the reaction of **18** with 2,6-xylylisonitrile under photochemical conditions afforded imine **20** in good yield and high α-selectivity.³⁹ The known steric influence of

the C-2 substituent has also been observed in this imidoxylation reaction; a bulky *N*-phthalimido group at this position reverses the stereochemical outcome to form β-C-glycosides exclusively. The reaction of pentopyranosyl and hexopyranosyl tellurides with electron-deficient heteroaromatic bases has been studied by Togo and Yokoyama and C-nucleoside analogs have been synthesized in moderate yields.⁴⁰

Scheme 3 Synthesis of C-glycosides by intermolecular trapping of glycosyl radicals with unsaturated compounds using transition-metal reagents. tmc, tetramethylcyclam; COD, 1,5-cyclooctadiene; bpy, 2,2'-bipyridyl; DMDO, dimethyl dioxirane.

Several coordination complexes and salts of the transition metals such as Ti(III) (see **Epoxides in Titanocene-Mediated and -Catalyzed Radical Reactions**), Ni(II), Ru(II), Cr(II), and Sm(III) (see **Organic Synthesis Using Samarium Diiodide**) have been used in the formation of anomeric radicals from glycosyl halides, and some examples are outlined in Scheme 3. Spencer and Schwartz have demonstrated that titanocene(III) chloride, a mild, nontoxic, and relatively inexpensive reducing reagent, is effective in the diastereoselective conversion of glucosyl bromide **21** into C-glycosides.^{41,42} The anomeric radical rather than an intermediate organotitanium species seems to be involved. In case of hexopyranosyl halides, when methyl vinyl ketone, methyl acrylate,

and acrylonitrile are used as radical traps, exclusive α -selectivity has been observed in the addition products **22–24**. 1-Gluco-, 1-manno-, and 1-galacto-pyranosyl radicals can also be generated from the corresponding bromides using nickel(II) salts as catalysts. For example, the reaction of glucosyl bromide **21** with Ni(tetramethylcyclam)₂(BF₄)₂ (20 mol%) and an excess of manganese dust with methyl methacrylate as an electron-deficient radical acceptor gave α -C-glycoside **25** in excellent yield.⁴³ Gagné have reported another stereoselective method for the Ni-catalyzed synthesis of α -C-alkylglycosides.^{44,45} The reaction of benzoyl glucosyl bromide **26** with methyl methacrylate using catalytic Ni(COD)₂ complex as precursor, (R)-Ph-pyBox as ligand, Zn dust as terminal

Scheme 4 Synthesis of *C*-glycosides via glycosyl-1-yl samarium intermediates.

reductant, and *i*Pr₂CHOH as proton source afforded α -*C*-glycoside **27** in high yield and diastereoselectivity. The same authors recently reported that irradiation of glucosyl bromide **21** with visible light in the presence of an excess of Hantzsch ester **28** and catalytic amounts of Ru(bpy)₃(BF₄)₂ generated glucopyranosyl radicals that reacted intermolecularly with electron-deficient olefins to provide α -*C*-glycosides **23**.⁴⁶ Several hydrolytically sensitive glycosyl halides of hexopyranose and pentopyranose series of carbohydrates have been transformed into *C*-glycosides with [Cr^{II}(EDTA)]²⁻ and electron-deficient alkenes under mild aqueous reaction conditions. For example, the two-phase reaction of an aqueous solution of the chromium complex and the glucosyl bromide **21** and acrylonitrile in ethyl acetate afforded the *D*-glycero-*L*-gulo-nonononitrile derivative **24**.⁴⁷ The anomeric radical produced by the reductive ring-opening of 1,2-anhydro sugars with titanocene(III) chloride can be trapped with electrophilic olefins to give exclusively α -*C*-glycosides such as **30**, with the free hydroxyl group at C-2 available for further elaboration.⁴⁸ The reaction proceeded in two steps from the corresponding

glycal **29** by preliminary epoxidation with dimethyl dioxirane (DMDO).

Sinaÿ in 1993 reported that reductive samarium of 2-deoxy- α -D-*arabino*-hexopyranosyl chloride **31** by the SmI₂/hexamethylphosphoramide (HMPA) system in the presence of cyclopentanone provided the corresponding α -*C*-glucoside **32** in high yield (Scheme 4).⁴⁹ They also found that under these conditions α -D-glucopyranosyl phenyl sulfones and bromides gave mainly 1,2-elimination products. In the absence of carbonyl compounds 1,2-elimination occurs exclusively and glucals are formed in synthetically useful yields.⁵⁰ Subsequently, Beau and Skrydstrup have thoroughly studied the samarium diiodide reduction of glycosyl pyridyl sulfones with aldehydes or ketones for the stereospecific formation of 1,2-*trans*-*C*-glycosides.^{51,52} Mannosylpyridyl sulfones such as **33** gave α -*C*-glycosides **34** in good yield, while glucosyl and galactosyl pyridyl sulfones gave β -*C*-glycosides only in moderate to low yields. In this last case, the major by-product was the corresponding glucal and the reaction needed to be catalyzed with NiI₂ to prevent the 1,2-elimination drawback.⁵³ Similarly, Hung and Wong⁵⁴ used samarium of

mannosyl phosphate **35** with simple aldehydes to give α -C-mannoside **36**. The two-step/one-pot DMDO oxidation– $\text{SmI}_2/\text{NiI}_2$ intermolecular reductive coupling sequence of glycals, such as **29**, with carbonyl compounds developed by Chiara and Sesmilo⁵⁵ provides a new methodology for the synthesis of 2-hydroxy C-glycosides **37**. The stereoselectivity, which can be significantly modified by the addition of a proton source, was also very sensitive to steric effects. With aldehydes, α -C-glycosides were predominantly or exclusively obtained, whereas ketones gave the corresponding β -isomers as major products.

Motherwell⁵⁶ has prepared difluoromethylene-linked C-glycosides and C-disaccharides by addition of electrophilic and nucleophilic radicals

to *gem*-difluoro-*exo*-glycals. The reaction of gulofuranose derivative **38** with 6-deoxy-6-iodo-glucopyranose **39**, under the tin hydride system, to give *gem*-difluoro-C-disaccharide **40** is representative of the addition to nucleophilic radicals (Scheme 5). The use of electrophilic radicals gave somewhat better results; thus the reaction of **38** with ethyl bromoacetate afforded α -C-glycoside **41** in 51% yield. As an interesting extension of this approach, the authors have reported the addition and concomitant 5-*exo*-trig ring closure of allyl iodomalonate **42** to *exo*-glycal **38** to afford the 1-oxaspiro[4.4]nonane bicycle derivative **43** in a one-pot, two-step sequence. Two new routes to α - CF_2 -glycosides by the addition of difluoromethyl radicals to 2-*O*-alkoxy glycals have been described.

Scheme 5 Synthesis of C-glycosides by intermolecular addition of alkyl radicals to unsaturated carbohydrate acceptors.

Miethchen⁵⁷ prepared 1,1-difluoroheptitol **45** by reaction of 2-*O*-acetyl-1,5-anhydrohex-1-enitol **44** with bromochlorodifluoromethane in the presence of sodium dithionite, which acts as radical initiator but also as reducing agent. In the other approach, the triethylborane-mediated reaction of ethyl bromodifluoroacetate with 2-*O*-benzyl glycols to give 2,2-difluoro-4-ulosonic ester **46** has been developed by Leclerc.⁵⁸

2.2 Synthesis of C-Disaccharides

Since Giese and Witzel published their seminal work in 1986,⁵⁹ radical chemistry has been transformed into a useful alternative for the synthesis of *C*-disaccharides, which are important nonhydrolyzable *O*-disaccharide mimetics with

potential activity as enzymatic inhibitors. The utility of Giese *C*-glycosylation is exemplified by the synthesis of the analog of kojibiose α -D-Glcp-(1 $\rightarrow$ 2a)-2a-carba- α -D-Glcp **48** by reaction of the α -methylene lactone **47** with glucosyl bromide **21** (Scheme 6). The intermolecular radical addition occurs in 70% yield with high diastereoselectivity.⁶⁰ Vogel has used this tin-based methodology to add a number of glycosyl halides to enone **50**, a versatile chiral synthon prepared from a “naked sugar”.⁶¹ The radical addition products were subsequently and conveniently transformed into *C*-disaccharides by a multistep sequence. For example, the reaction with mannosyl bromide **49** afforded α -D-Manp-(1 $\rightarrow$ 3a)-3a-carba-D-GalpNAc **51**, while a slight modification of the synthetic procedure permitted the *C*-2 isomer α -D-Manp-(1 $\rightarrow$ 3a)-3a-carba-D-TalpNAc to be prepared. Another example of the

utility of unsaturated ketones as acceptors and the tin hydride method is the reaction of 2,6-anhydro-1-deoxy-1-iodo-D-*glycero*-D-*gulo*-heptitol with levoglucosenone to give β -D-Glcp-(1 $\rightarrow$ 4a)-4a-carba-3-deoxy-D-Glcp due to Witczak *et al.*⁶²

Over the past several years, Beau and Skrydstrup^{51–53,63–70} have conducted a detailed study on the samarium diiodide reduction of glycosyl pyridyl sulfones with carbohydrate aldehydes under Barbier conditions which led to the intermolecular formation of *C*-disaccharides in a highly efficient and stereoselective manner. With regard to the samarium mechanism, the reduction of the glycosyl sulfone is believed to proceed through two consecutive one-electron processes. The resulting anomeric organosamarium species subsequently adds to the carbonyl compound. The reaction proceeds efficiently in the manno series to give 1,2-*trans*-*C*-disaccharides in high yield and excellent diastereoselectivity. In the gluco and especially in the galacto series, the presence of NiI₂ as a catalyst is necessary; otherwise, significant amounts of 1,2-eliminated products (glycals) are obtained.⁵³ As a representative example, the samarium of 2-pyridyl sulfone **33** in the presence of aldehyde **52** to give *C*-disaccharide **53** in good yield is shown in Scheme 6.^{51,52} The use of a glycosyl phosphate group **54** as an

acceptor in the initial electron-transfer reaction and subsequent addition to aldehyde **55** to give the α -D-Manp-(1 $\rightarrow$ 6a)-6a-carba- α -D-Glcp derivative **56** has been proposed by Hung and Wong.⁵⁴ *C*-Disaccharides with the four possible linkages (1 $\rightarrow$ 2a), (1 $\rightarrow$ 3a), (1 $\rightarrow$ 4a), and (1 $\rightarrow$ 6a) have been prepared using this methodology, and the structures and yields are summarized in Table 1 (Entries 1–12). Of special interest are the samarium of D-GlcpNAc which gave a *C*-disaccharide with an anomalous 1,2-*cis* disposition preferentially, attributable to strong complexation between the *N*-acetamido group and the samarium ion (Entry 6), the Ni(II)-catalyzed reactions (Entries 7–10), and the synthesis of a *C*-trisaccharide in a single step from a 3,6-diformylmanno derivative (Entry 11). Since the first synthesis of an α -*C*-disaccharide of *N*-acetylneuraminic acid by Linhardt in 1997,⁷¹ a number of these compounds have been prepared, which are given in Table 1 (Entries 13–17). In a recent example, the 2-pyridyl sulfide of the Neup5Ac derivative **57** reacts with aldehyde **58** in a type of samarium-Reformatsky process to give stereoselectively **59** (Scheme 6).^{69,70} The procedure worked equally well with anomeric pyridyl sulfones of 3-deoxy-D-manno-2-octulosonic acid as donor using 6-formylgalactopyranoside as acceptor to give the α -*C*-disaccharide

of KDO [α -Kdop-(2 $\rightarrow$ 6a)-6a-carba- α -D-Galp] (Entry 17).⁷²

2.3 Synthesis of C-Ketosides

C-Ketosides (bis-C,C-glycosides) are a class of carbohydrate analogs that have received increased attention of synthetic chemists owing to their relationship with C-glycosides of ulosonic acid and as versatile chiral synthons for a large range of natural complex molecular synthesis.

Since the first reports on the use of a reductive denitration of 1-nitro-C-glycosides **60** by Giese *et al.*^{15,74} in 1985, a few more examples have been found in the literature for the preparation of C-ketosides under radical intermolecular conditions, which are outlined in Scheme 7. The introduction of the required two tethers in a single step has been achieved by Praly⁷⁵ by reaction of 1-bromo- β -D-glucopyranosyl chloride **5** with

an excess of allyltributylstannane. The diallyl compound **61** was subsequently transformed into an anomeric spiro sugar (6-oxaspiro[4.5]dec-2-ene system) by way of ring-closing metathesis (RCM). C-Ketosides based on D-glucose, D-manno, and D-galacto series of N-acetyl-2-amino sugars **62** have been prepared by homolytic cleavage of the C–Se bond and α -trapping the resulting anomeric radical with *tert*-butyl acrylate and under Keck allylation conditions with allyltributylstannane. Styrene, which is not an efficient trapping agent for anomeric nucleophilic radicals, was also used, although, as expected, the corresponding addition product was obtained in low yield (29%).⁷⁶ The reaction can also be extended to seleno-C-glycoside **63**, the interesting carbohydrate-based δ -amino acid derivative **64** being obtained as a single diastereomer. A diastereoselective synthesis of the starting compound **63** has been achieved using a radical azidoselenation of *exo*-glycals as the key step (see **193** in Scheme 26).⁷⁷ The preparation of C-ketosides from N-acetylneuraminic acid and other ulosonic

Scheme 7 Synthesis of C-ketosides by intermolecular addition of C-glycos-1-yl radicals to double bonds.

acid derivatives has been extensively studied. A variety of anomeric substituents such as chloride,⁷⁸ phenyl sulfone,⁷⁹ 2-pyridyl sulfide,^{69,70} 2-pyridyl sulfone,⁷¹ and acetate **65**⁸⁰ are useful precursors through reductive samarium in the presence of carbonyl compounds (see also **2** in Scheme 1).

2.4 Synthesis of Branched-Chain Sugars

Cerium(IV) ammonium nitrate (CAN) mediated radical addition of malonates (see **Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry**) to glycals has been thoroughly investigated by Linker⁸¹ and constitute a

general and convenient strategy for the synthesis of 2-C-malonyl carbohydrates. The reaction has been applicable to glycals of the hexose and pentose series and to disaccharide systems, and the corresponding 1,2-trans addition products were always obtained. For instance, acetyl glucal **66** with anhydrous CAN in methanol afforded a mixture of methyl β -D-glucoside **67** and α -D-mannoside **68** in excellent yield (Scheme 8). This work follows the pioneering CAN-mediated radical azidonitration of glycals by Lemieux and Ratcliffe.⁸² The benzophenone-initiated photoaddition of methanol to endocyclic conjugated α -enones developed by Fraser-Reid⁸³ provides a method for the preparation of C-2 and C-4 branched

Scheme 8 Synthesis of branched-chain sugars. DLP, dilauroyl peroxide.

Figure 3 Ring-closure of 5-hexenyl and 6-heptenyl radicals. Rate constants taken from Ref. 89.

sugars such as **69**. The analogous additions of isopropanol to carbohydrate γ -lactones have been reported by Mann and Weymouth-Wilson.⁸⁴ The one-carbon extended C-glycosylation of Kim,³³ already described in Scheme 2, has also been applied by the authors to C-2, C-3, and C-6 positions of the sugar skeleton. For instance, ultraviolet irradiation of 3-iodo-D-mannoside **70** in the presence of phenylsulfonyl oxime ether **12** provided C-3-branched-chain glycoside **71** with total inversion of configuration. Postema *et al.*,⁸⁵ during the development of a general methodology for the synthesis of β -C-disaccharides by RCM, prepared C-2, C-3, and C-4 allyl branched-chain sugars. The reaction of iodine glycoside **72** with allyltributylstannane under Keck allylation conditions afforded a mixture of D-Glc/D-Gal **73** in a diastereomeric ratio, 6:1. Similarly, Castellón⁸⁶ also used Keck conditions to prepare C-3 and C-4 allyl-substituted carbohydrates such as 3-allyl-D-glucoside **75** from the 3-O-xanthate **74**. We have also included in this section the new strategy for the synthesis of naturally occurring C-aryl glycosides that has been developed by Cordero-Vargas *et al.*⁸⁷ The xanthate-mediated radical addition–cyclization sequence (see **Xanthates and Related Derivatives as Radical Precursors**) of xanthate **77** onto olefin **76** afforded tetralone **78**, which was subsequently aromatized.

frameworks by intramolecular cyclization of acyclic carbohydrates has received considerable attention among synthetic organic chemists.⁶ By far, the most frequently used radical cyclizations involve the formation of five- and six-membered rings. According to the Baldwin rules, 5-hexenyl **I** and 6-heptenyl **IV** radicals cyclize predominantly through favored *exo*-trig processes to give the smaller rings **II** and **V**, respectively, the minor products **III** and **VI** being formed by *endo*-trig cyclizations (Figure 3).⁸⁸ The 5-hexenyl **I** and 6-heptenyl **IV** cyclization reactions proceed under kinetic control to give the thermodynamically less stable primary radicals **II** and **V** much faster than the secondary radicals. Beckwith has explained this regioselectivity on the basis of steric and stereoelectronic effects, suggesting that a major factor is the strain engendered in the transition states (TSs).^{89,90} The regioselectivity changes if the 5-hexenyl radical cyclization is reversible and the reaction is run under thermodynamic conditions; six-membered rings are formed predominantly.⁹¹ Substitution at the double bond or the presence of a silicon group in the chain can also favor the formation of six-membered rings.¹⁸ Calculated TSs for the ring closures of ω -alkenyl radicals have been extensively studied by different computational methods and are in excellent agreement with the stereo- and regioselectivity observed.⁹²

3 INTRAMOLECULAR CARBON–CARBON BOND-FORMING PROCESSES

The ability of free-radical chemistry to construct polyfunctionalized carbocyclic and heterocyclic

3.1 Synthesis of C-Glycosides

C-Glycosides can be prepared by the addition of a glycos-1-yl radical donor onto an acceptor group suitably anchored to the sugar ring by

Scheme 9 Synthesis of *C*-glycosides by intramolecular addition of glycos-1-yl radicals to an unsaturated acceptor. TBAF, tetrabutylammonium fluoride.

carbon or heteroatom linkage. An early example of this methodology is the formation of bicyclic dideoxy sugars by intramolecular radical cyclization after Giese.⁹³ De Mesmaeker *et al.*,⁹⁴ Hung and Wong,⁵⁴ Sinaÿ,⁵⁰ and Czernecki *et al.*⁹⁵ took advantage of this protocol for the synthesis of different cyclic *C*-glycosides **80–82** (Scheme 9). De Mesmaeker demonstrated, moreover, the usefulness of an easily removable acetal-linked group in **79** to obtain an acyclic 1,2-*cis*-*C*-glycoside through the corresponding fused cyclic α -*C*-glycoside **82**.⁹⁶ A noteworthy extension of this strategy by Stork achieves this challenge by the cyclization of an acceptor group tethered to the sugar ring through a temporary silicon linkage, such as **83**.⁹⁷ Subsequently, Skrydstrup and Beau demonstrated that the silicon-tether approach is also compatible with samarium diiodide reduction of mannosylpyridyl sulfone **84** to develop stereocontrolled radical cyclizations.⁹⁸

Sinaÿ transferred this temporary silicon linkage methodology to the synthesis of α -^{99–103} and β -*C*-disaccharides^{104,105} based on eight or

nine *endo*-trig radical cyclizations from two silaketal-tethered linked monosaccharides. The selective synthesis of a β -*C*-disaccharide **85** was accomplished successfully through an eight-membered TS (Scheme 10).¹⁰⁵ Shuto planned to use this type of radical coupling reaction for synthesizing α -*C*-glycosidic analogs of natural adenophostin A.¹⁰⁶ The tin-promoted glucopyranos-1-yl radicals from **86** triggered a nine-membered TS cyclization to give the α -*C*-disaccharide **87** in good yield and modest diastereoselectivity. A similar process for the 1,2-*cis*-*C*-disaccharide generation is also achievable using samarium diiodide. Starting from suitable anomeric radical precursors such as sulfones **88** and **90**, α -*C*-disaccharides **89**¹⁰⁷ and **91**^{98,108} were obtained, respectively.

3.2 Synthesis of *C*-Ketosides

We envisaged a simple methodology for the preparation of *C*-ketosides, using an intramolecular HAT reaction as the key step.¹⁰⁹ A conveniently

Scheme 10 Synthesis of C-disaccharides by intramolecular addition of carbohydrate radicals to an unsaturated acceptor, using a temporary silicon linkage. ^aOverall yield from starting monosaccharides.

disposed alkoxy radical generated from phthalimide **92** would trigger the HAT reaction, and the C-radical intermediate could be added to allylstannane to give C-ketoside **93** as depicted in Scheme 11. The stereochemistry of the quaternary carbon, carrying two differently functionalized tethers, is stereoelectronically controlled and independent of that of the starting isomer. In

a recent work, we prepared new spirocyclic C-ketoside derivatives by a diastereocontrolled Norrish–Yang photocyclization of 2,3-diulose **94** (see **Synthetic Radical Photochemistry**).¹¹⁰ The 2-hydroxy-cyclobutanone **95** intermediate could be converted into γ -ketoester **96** through oxidative ring cleavage with periodic acid.

Scheme 11 Intramolecular synthesis of C-ketosides.

Scheme 12 Synthesis of branched-chain sugars by intramolecular addition of tethered radicals to unsaturated carbohydrates.

3.3 Synthesis of Branched-Chain Sugars

For the introduction of carbon chains on a carbohydrate template, two main approaches can be considered. In the first one, an unsaturated sugar model acts as a radical acceptor while a C radical is generated on a tether carbon chain. The reverse principle is applied in the second version, in which the radical donor is generated on the sugar template and cyclizes onto a tether radical acceptor. The radical addition on unsaturated carbohydrates has been successfully used with 2,3-, 3,4-, and 4,5-unsaturated sugars to form C-2, C-3, and C-4 branched-chain carbohydrates (Scheme 12). In the first example, De Mesmaeker studied the stereochemical outcome of the 5-*exo*-trig cyclization to form *cis*-fused 4*H*-furo[2,3-*b*]pyran bicycle **97**.¹¹¹ Similarly, Chapleur¹¹² and Fraser-Reid¹¹³ used the radical cyclization of temporary α -halogen acetal tethers to synthesize C-2 or C-3 branched-chain sugars with predictable stereochemistry. The reaction of iodo acetal **98** to give α -fused product **99** is illustrative.¹¹² Furthermore, Chapleur also demonstrated that vinylic radicals, generated by

tributyltin hydride addition on triple bonds, add efficiently on 2,3-double bonds.¹¹⁴ In recent times, Kelly and Picton¹¹⁵ and Chiara¹¹⁶ have proficiently used this methodology. The Chiara application is shown for the stereoselective synthesis of **100**, the glycosidic moiety of antifungal GM222712. The strategy of the silyl ether temporary linkage, developed by Nishiyama *et al.*¹¹⁷ and Stork and Sofia,¹¹⁸ was used by Sinay,¹¹⁹ Herdewijn,¹²⁰ and Fraser-Reid.¹¹³ This procedure has been successfully employed for the hydroxymethylation of sugars at positions 3, 4, and 6. The synthesis of 4-deoxy-4-hydroxymethyl- β -D-galactose derivative **101** is a representative example.¹¹⁹

Radical addition to an unsaturated carbohydrate model generates an intermediate C radical located on the sugar template which may subsequently add inter- or intramolecularly to a new radical acceptor via a serial radical process. The pioneering works on sequential radical cyclization–intermolecular trapping reactions were developed by Ferrier and Petersen¹²¹ on differently tethered unsaturated sugar derivatives, such as **102**, and Fraser-Reid¹¹³ during the reaction

Scheme 13 Synthesis of branched-chain sugars by sequential addition of radicals to unsaturated carbohydrates.

of glycal **103** with enone **104** (Scheme 13). Alternative intramolecular trapping processes were described by Fraser-Reid¹²² for the stereocontrolled synthesis of Woodward's densely functionalized intermediate **105** for reserpine synthesis and by Kelly and Picton¹²³ who reported successful alkyne–alkene–alkene and alkyne–alkene–alkyne tin-initiated catalytic cascade tricyclizations, in which the three new rings are constructed in a single step. The cyclization of 4-*O*-allyl-1-*O*-propargyl sugar **106** produced the expected tetracycle **107** and an additional noncatalytic compound **108**.

In the second version of the intramolecular synthesis of branched carbohydrates, the radical is generated on the sugar template and adds to an exocyclic acceptor. As in the preceding approach, several different connections of the acceptor partner onto the sugars, such as acetal,^{124–128} ether,^{63,129} carbon,^{130–132} or silyl linkages,^{133,134} have been used. The pioneering works for the synthesis of C-2 branched pyranosides where the radical acceptor is linked by an acetal group came from Beau¹²⁴ and De

Mesmaeker *et al.*,¹²⁵ who used *O*-alkenyl (such as **109** or **110**) or alkynyl iodo glycosides to synthesize cis-fused bicycles by treatment with *n*Bu₃SnH (**112** or **113**, respectively), confirming that the cyclization is under kinetic control and proceeds exclusively via the favored *exo* mode (Scheme 14). Consequently, Togo used a similar synthetic approach from glycoside **111** to bicyclic sugar **112**, but using Ph₄Si₂H₂ which is a less toxic radical reagent.¹²⁶ Moreover, Hoffmann developed a stunning radical tandem cyclization of 2β-iodo glucopyranosides **114**.¹²⁷ The process afforded doubly annulated enantiomerically pure glycoside **115**, in a 5-*exo*-trig, 6-*endo*-dig cascade. Subsequently, Choe and Jung described a new method to prepare 2-formyl-glucoside **116** employing a radical formyl transfer process driven by the formation of a stable benzyl radical.¹²⁸ This was similarly used by Skrydstrup and Beau to prepare 2-formyl-mannopyranoside **117**, this time using an ether connection to the carbohydrate sugar at C-3.⁶³ Ongoing with the ether linkage, Sharma achieved the first total synthesis of xylobovide by an

Scheme 14 Synthesis of C-2 branched-chain sugars by intramolecular addition of radicals positioned on the carbohydrate skeleton to unsaturated tethers.

intramolecular radical cyclization-based route promoted by a xanthate precursor **118**.¹²⁹

The earliest works for the synthesis of branched pyranosides in which the radical acceptor is linked to the sugar by a carbon atom are from Hashimoto for the synthesis of cyclopentane-annelated pyranosides.¹³⁰ Subsequently, Fraser-Reid took advantage of this strategy for preparing densely functionalized natural products or segments thereof from carbohydrate precursors as shown in Scheme 15 for the synthesis of the tricyclic dihydrofuran portion of azadirachtin **119**.¹³¹ Chattopadhyaya developed an intramolecular free-radical ring-closure

reaction between a radical generated at C-2 and a distant C=N double bond of an oximino-ether **120**.¹³² Finally, some appealing approaches to branched-chain nucleosides have also been described.^{133–135} Chattopadhyaya used silicon-tethered acetylene to accomplish a 5-*exo*-trig cyclization giving exclusively the *cis*-fused isomer **121**.¹³³ Some studies implemented by Matsuda¹³⁴ and Mayon and Chapleur¹³⁵ on *O*-linked vinyl-silicon tethers emphasize that the presence of a silicon atom in the tether strongly influences the cyclization process. The thermodynamic 6-*endo* product **122** is formed only at low concentration of

Scheme 15 Synthesis of branched-chain sugars by intramolecular addition of radicals positioned on the carbohydrate skeleton to unsaturated tethers. MMTr, 4-monomethoxytrityl; DMTr, 4,4'-dimethoxytrityl.

hydride; at higher concentrations the corresponding 5-exo product was exclusively produced.¹³⁴

Marco-Contelles¹⁴⁰ can also be found in the literature.

3.4 Synthesis of Carbocycles from Acyclic Sugar Derivatives

Carbasugars, previously known as *pseudosugars*, are a family of carbohydrate mimics that has been attracting great interest among chemists and biochemists for the last two decades.¹³⁶ They are structurally similar to normal sugars, although the hemiacetal ring oxygen has been replaced by a methylene group. Gómez and López have recently reported a comprehensive review that exemplifies the progress made in the synthesis, conformational studies, and biological aspects of carbasugars.⁶ Earlier reviews by Fraser-Reid and Tsang,¹³⁷ Ferrier,¹³⁸ RajanBabu,¹³⁹ and Martínez-Grau and

3.4.1 Synthesis of Carbafuranoses and Polyfunctionalized Cyclopentane Analogs

The 5-exo cyclization is especially useful for the synthesis of cyclopentanes. In this field, Wilcox developed the first example of the radical 5-exo-trig cyclization derived from unsaturated halo-aldoses to prepare epimeric cyclopentanes **123** and **124** (Scheme 16).¹⁴¹ It was observed that the cyclization of the *Z* isomer proceeded with a greater degree of stereocontrol and the major product had an exo orientation of the ester group. In a similar reaction, Kita found that the use of V-70L instead of AIBN as radical initiator made it possible to achieve a higher stereoselective synthesis

Scheme 16 Synthesis of cyclopentane derivatives via 5-*exo*-cyclizations with tin reagents.

of **123** and **124**.¹⁴² Roberts used an analogous methodology to synthesize different carbafuranoses starting also from primary haloderivatives,¹⁴³ while Lundt applied a related strategy for the synthesis of carbapentofuranoses such as **125** starting from bromodeoxyheptonolactones.¹⁴⁴ Similarly, Leclerc devised a general route to difluorinated carbocyclic 5-deoxypentofuranose analogs **126** but using a phenylselenenyl group.¹⁴⁵ In a related study, RajanBabu successfully employed secondary imidazole carbothioate **127**, observing that the corresponding hex-5-enyl radical cyclizes efficiently with exclusive formation of a cis-fused bicyclic system and 1,5-trans stereochemistry.¹⁴⁶ Bartlett opened up a straightforward approach to aminocarbafuranoses as **128** using a radical cyclization of carbohydrate-derived oxime ethers.¹⁴⁷ This procedure has been extended subsequently by a number of groups for the preparation of aminocyclopentitols.¹⁴⁸ Hanessian reported that trimethylstannyl radicals add to the unsubstituted terminal olefinic carbon atom of activated and

unactivated dienes to produce cyclopentane compounds such as **129** with the preponderance of the isomer with a syn orientation of the carbon substituents.¹⁴⁹ Similarly, Marco-Contelles disclosed the first examples of $n\text{Bu}_3\text{SnH}$ -promoted free-radical cyclization of δ -alkynyl tethered oximes, imines, and N,N -disubstituted hydrazones to provide a simple synthesis of enantiomerically pure aminocyclitol derivatives as **130** in moderate yields.¹⁵⁰ The 5-*exo*-dig radical cyclization of 1,2,6-trideoxy-6-iodo-*L*-arabino-hex-1-ynitol **131** could be a useful method to prepare exocyclic methylene cyclopentanes in good yields.¹⁵¹

A useful alternative to trialkyltin hydride-based reductive coupling is supplied by one-electron reducing agents such as samarium diiodide. In a pioneering approach to carbafuranoses, Enholm described, in 1989, the stereoselective SmI_2 -mediated intramolecular cyclization of aldehydes and electron-deficient alkenes, as depicted in **132**, to give cyclopentanols (Scheme 17).¹⁵² It was observed that a cis-olefin in the starting

Scheme 17 Synthesis of cyclopentane derivatives by SmI_2 -mediated reductive coupling.

substrate favored a syn product, while a trans-olefin gave preferably the anti product. More recently, Holzapfel¹⁵³ and Matsuda¹⁵⁴ have also applied this methodology to convert selectively substituted carbohydrates into the analogous stereodefined cyclopentanols. Subsequently, Zhou and Bennett¹⁵⁵ used the SmI₂/HMPA system to perform the radical cyclization of D-ribonolactone-derived alkenyl halides **133**. Sinaý reported in 1995 a SmI₂-promoted stereoselective ring contraction of methyl hexodialdo-pyranosides to give highly functionalized cyclopentanes.¹⁵⁶ More recently, this method was applied by Jenkins and Potter¹⁵⁷ and Iadonisi¹⁵⁸ to develop a pinacolization in carbohydrate derivatives and by Sinaý¹⁵⁹ to give an

inseparable mixture of two cis-diol intermediates **134** and **135** in the total synthesis of calditol. The Giese¹⁶⁰ and Chiara *et al.*¹⁶¹ groups have described one of the most suitable methods for the synthesis of aminocyclopentitols such as **136** by SmI₂-based reductive couplings of polyhydroxylated oxime ethers¹⁶² or *N,N*-disubstituted hydrazones¹⁶³ in studies toward the synthesis of trehalamine.

Besides samarium diiodide, there are also other alternatives to tributyltin hydride-promoted reductive coupling, such as the use of tellurium, cobalt, mercury, and titanium derivatives (Scheme 18). Barton designed a new source of alkyl radicals by radical exchange.¹⁶⁴ The process involves the use of

Scheme 18 Alternatives to tin and samarium reagents for the synthesis of cyclopentane derivatives. An, anisyl.

the acetyl derivative of *N*-hydroxy-2-thiopyridone **138** as a convenient source of methyl radical which can react with an anisyltelluride derivative such as **137** to afford the desired alkyl radical intermediate. This C radical is able to cyclize intramolecularly with a proper olefin to generate the corresponding carbocycle. On the other hand, Prandi developed a cobalt-catalyzed radical cyclization of 6-iodohex-1-enitol derivative **139** to give the expected hydroxymethyl-substituted cyclopentane **140**.¹⁶⁵ A process involving chemoselective mercuriation of diene **141**, followed by reductive radical cyclization, has been described by Gallos for the synthesis of carbocycle **142**.¹⁶⁶ Chiara has

shown that the reductive cross-coupling of epoxides with carbonyl groups promoted by titanocene chloride can also be successfully applied to the stereoselective synthesis of highly functionalized branched cyclitols such as **143** and **144** from readily available hexose precursors.¹⁶⁷ Recently, we developed a conceptually different approach for the synthesis of branched cyclopentitols such as **146** by photolysis of 4,8-anhydro-2,3-diuloses. The proposed mechanism implies a HAT reaction promoted by a Norrish type II photoelimination followed by a highly diastereoselective thermally induced enolexo aldol cyclization of an isolable photoenol intermediate **145** which acts as a preformed enolate.¹⁶⁸

Scheme 19 Synthesis of cyclohexane derivatives.

3.4.2 Synthesis of Carbapyranoses and Polyfunctionalized Cyclohexane Analogs

The cyclization of 6-heptenyl radicals proceeds much more slowly than that of the 5-hexenyl radicals (Figure 3). In consequence, there are relatively few examples for the preparation of carbapyranoses by 6-*exo* or 6-*endo* radical ring closure.

Although the first examples of the synthesis of a 5a-carbapyranose by 6-*exo*-trig radical cyclization were published almost simultaneously by Samuelsson¹⁶⁹ and Schmid and Whitesides,¹⁷⁰ Redlich reported a comprehensive study on the scope of the radical ring closure of 7-deoxy-7-iodohept-1-enitols as **147** leading to several 6-deoxy-5a-carbapyranoses (Scheme 19).¹⁷¹ Marco-Contelles showed that, if the 6-*exo*-trig radical cyclization occurs on an α,β -unsaturated ester,¹⁷² an enol-ether double bond,¹⁷³ or an oxime¹⁷² the resulting carbasugars are useful building blocks for the preparation of differently substituted inositols. On other hand, Lundt extended the previous work developed on carba-furanoses¹⁴⁴ to 8-bromo-8-deoxy-oct-2-eno-1,

4-lactones for the regio- and stereoselective preparation of carbapyranoses **148**.¹⁷⁴ Yadav reported the first examples of the 6-*exo*-trig radical cycloisomerization of polyoxygenated alkyne-tethered aldehydes, of the type depicted by **149**, to prepare (+)-*allo*-quercitol and (+)-*talo*-quercitol with high diastereoselectivity.¹⁷⁵ The synthesis of carbasugars involving 6-*exo*-dig radical cyclization was first shown by McDevitt and Fraser-Reid¹⁷⁶ and afterward by Wightman.¹⁷⁷ More recently, Gómez and López have studied the different factors that favor the 6-*endo* versus 5-*exo* radical ring closure to lead to carbapyranoses.¹⁷⁸ They found that enyne **150**, which includes at least two regiodirecting features (vinyl radical and substitution at C-5), is able to undergo 6-*endo*-trig radical cyclization in good yields. Since the original works by Chiara and Martín-Lomas¹⁷⁹ and Mioskowski¹⁸⁰ on SmI₂-promoted pinacol coupling in a carbohydrate 1,6-dialdehyde to provide an inositol ring, others such as Kornienko and d'Alarcao¹⁸¹ or Matsuda¹⁸² have recently performed further studies in this field. As a representative example, the synthesis of a *myo*-inositol derivative **151** from a D-xylose derivative is shown in Scheme 19.¹⁸¹

Scheme 20 Synthesis of four-, seven-, and eight-membered carbocycles.

3.4.3 Synthesis of Four-, Seven-, and Eight-Membered Carbocycles

Chiral, nonracemic cyclobutanols form integral parts of various antiviral and sedative agents. In this field, Williams developed a procedure for the conversion of carbohydrate precursors into highly functionalized cyclobutanes employing SmI_2 by pinacol coupling,¹⁸³ or 4-*exo*-trig cyclization, as in **152** (Scheme 20).¹⁸⁴ On other hand, an emerging interest in the preparation of carbasugars containing rings larger than five or six members has arisen in recent years. In the radical approach, Marco-Contelles has described 7-*exo* and 8-*endo* free-radical carbocyclization of acyclic radical precursors derived from sugars for the synthesis of highly functionalized medium-sized rings such as **153** and **154**.¹⁸⁵

4 CARBON–HYDROGEN BOND-FORMING PROCESSES

In this section, we focus our attention on the deliberated reduction, namely formation of carbon–hydrogen bonds concerning anomeric and

non-anomeric C radicals generated under reductive conditions in carbohydrate models of significant synthetic interest.

4.1 Synthesis of Anhydroalditols

Hydrogen quenching of anomeric C radicals constitutes a simple method not only for the synthesis of anhydroalditols but also for the stereoselective preparation of β -C- or β -O-glycosides and 2-deoxy-sugars. In this context, Praly in 2001 reported a comprehensive review that exemplifies the progress made in the structure of anomeric glycosyl radicals and their transformations under reductive conditions.¹⁴ Augé and David published the first example of radical synthesis of 1,5-anhydroalditols starting from glycosyl chlorides by treatment with $n\text{Bu}_3\text{SnH}$ and AIBN.¹⁸⁶ Later work by Kocienski employed more reactive glycosyl bromides and photochemical initiation.¹⁸⁷ Recent selected examples include the synthesis of the disaccharide 1,5-anhydromaltitol by Vismara¹⁸⁸ and the reduction of galactopyranosyl bromide **11** to give 1,5-anhydro-galactitol **155** in nearly quantitative yield by Thiem (Scheme 21).¹⁸⁹ In addition to glycosyl halides, 1,5-anhydrohexitols

Scheme 21 Synthesis of anhydroalditols.

have also been frequently prepared in good yields from phenylselenides,^{190,191} xanthates,¹⁹² or organotellurides,¹⁹³ among others. Apart from tin reagents, other alternative reductants such as tris(trimethylsilyl)silane (TTMSS) (see **Silanes as Reducing Reagents in Radical Chemistry**),¹⁹⁴ hypophosphorous salts,¹⁹⁵ and arylthiols¹⁹³ for the case of telluroglycosides have been used as well. Compared that of to 1,5-anhydrohexitols, the preparation of 1,4-anhydroalditols has received only limited attention, although a few examples can be found in the recent literature starting from anomeric xanthates.^{196,197} For instance, Wood¹⁹⁷ used a trialkylborane/air/water system to accomplish the radical-mediated deoxygenation of xanthate **156**. To analyze the stereoselectivity of the HAT reaction promoted by anomeric C radicals, some deuterium studies have been carried out. It was observed that in the $n\text{Bu}_3\text{SnD}$ reduction of α - and β -D-glucosyl and α -D-mannosyl halides, with the pyranose ring in $^4\text{C}_1$ chair conformation, the stereochemistry of the deuterium in the 1,5-anhydroalditol is very predominantly α -axial and independent of the stereochemistry of the starting halide.^{198,199} Recently, Shuto studied the stereoselectivity using conformationally $^1\text{C}_4$ -restricted glucose derivative **157**; deuteration by β -axial attack gave exclusively the β -deuterated product **158**.¹⁹¹ These results reflect that stereoelectronic effects play an important role in radical reactions at the anomeric center, as was commented upon in Section 2.

4.2 Stereocontrolled Synthesis of β -O- and β -C-Glycosides

There are two different main routes to give β -O- and β -C-glycosides. The first approach involves a single radical intermediate generated regioselectively and directly at the anomeric center. However, the second route engages a preliminary radical generated somewhere in the molecule which subsequently promotes a favorable regioselective hydrogen-atom abstraction at the anomeric center to lead to the corresponding anomeric C-radical intermediate formed by radical translocation. In both cases, the final hydrogen trapping of the anomeric C radical is the key step in terms of stereoselectivity.

4.2.1 Diastereoselective Hydrogen Quenching of Anomeric Radicals

Within the framework of this first approach, Kahne pioneered the application of alkoxy-substituted anomeric radicals for the synthesis of β -O-glycosides.²⁰⁰ These radicals were prepared from hemithio ortho esters such as **159** by treatment with $n\text{Bu}_3\text{SnH}$, observing that hydrogen quenching led preferentially to the β anomer in high yields (Scheme 22). Moreover, Crich²⁰¹ proved that the Barton radical decarboxylation of *O*-acyl thiohydroxamates of 2-ulopyranosonic acids, as depicted by **160**, gave the β -D-Manp-(1 $\rightarrow$ 6)- α -D-Glcp

Scheme 22 Synthesis of β -O- and β -C-glycosides.

disaccharide **161** with inversion of configuration at C-1'. Examples of these decarboxylations in the 2-ulofuranosonic acid series have also been reported by Crich and Ritchie²⁰² and Garner.²⁰³ Among C-glycosyl derivatives, those having halogen atoms or nitro groups attached to the anomeric center and thio- or seleno-glycosides are able to undergo radical-mediated reduction in the presence of tin or silicon hydrides as described earlier for the synthesis of β -C-glycosides (Schemes 1 and 7).²⁷ Aware that monothioketals are usually reduced with excellent stereoselectivity with tin hydrides, Kishi extended this procedure to C-disaccharide systems such as **162** to obtain exclusively the β isomer.²⁰⁴

4.2.2 Radical Translocation

The second approach to β -O- and β -C-glycosides involves a sequence of radical reactions involving first an intra- then an intermolecular HAT. This alternative has been applied almost exclusively

to manno- or rhamnopyranosides where a silyl or acetal linkage at C-2 could be particularly useful. Curran reported that α -mannoside **163** underwent radical translocation to give two products: the inverted β -mannoside **164** resulting from 1,6-HAT and α -glucoside **165** obtained via competing 1,5-HAT (Scheme 23).²⁰⁵ A similar approach starting from the mixed acetal **166** has been developed by Crich, but under their best conditions a relatively low anomeric inversion was obtained.²⁰⁶ We have also included in this section the translocation between O and C radicals observed in the reactions of phthalimides **167** and **170**. The alkoxyl radical generated from C-mannosyl glycoside **167** triggered a 1,6-HAT which afforded inverted β -C-glycoside **168** in moderate yield; by employing $n\text{Bu}_3\text{SnD}$ as reductant, it was evident that the major product **169** has been formed via a competitive 1,5-HAT process.²⁰⁷ Recently, in our laboratory we have implemented a translocation methodology based on an intramolecular 1,8-HAT reaction between the two pyranose units

Scheme 23 Radical translocation between carbon-carbon and carbon-oxygen radicals.

in suitably substituted (1 $\rightarrow$ 4)-*O*-disaccharides.²⁰⁸ The alkoxyl radical at C-6 was generated by reaction of an *N*-hydroxyphthalimide derivative, such as **170** (α -D-Manp-(1 $\rightarrow$ 4)- β -L-Gulp), with the *n*Bu₃SnH/AIBN system and the abstraction occurs exclusively at C- 5' with predominant inversion of configuration to give the disaccharide **171** (β -L-Gulp-(1 $\rightarrow$ 4)- β -L-Gulp).

4.3 Synthesis of 2-Deoxy Sugars by Radical-Induced 1,2-Ester Rearrangement

The 1,2-migrations of acyloxy and phosphonyloxy groups in the carbohydrate field involve initial generation of an anomeric C radical and its subsequent rearrangement to a C-2-centered radical which finally leads to 2-deoxy sugars.^{209,210} The thermodynamic driving force that explains this rearrangement is derived from the formation of the strong anomeric C–O bond despite the reduction step occurring through the less electronically stabilized C-2 radical. Giese was the first to expand this 1,2-migration to carbohydrates, observing that, starting from acetylated models, such as **21**, or benzoylated glycopyranosyl, or furanosyl halides or selenides, 2-deoxy sugars **172** were obtained in good yields by a cis-selective rearrangement (Scheme 24).^{211,212} It was also demonstrated that the slow addition of *n*Bu₃SnH required to avoid the direct reduction of the starting substrate may be circumvented by the

use of alternative reductants such as TTMSS.²¹³ A further alternative to tin hydrides was proposed by Quiclet-Sire and Zard,²¹⁴ using *S*-glycosyl xanthates, such as **173**, as radical precursors in refluxing cyclohexane, which surprisingly acts as an effective hydrogen donor, and dilauroyl peroxide (DLP) as initiator to give 2-deoxy carbohydrates **174** in good yields. In contemporaneous works, Crich and Giese firstly described phosphonyloxy radical migration in 1993.^{215,216} The preparative potential of this migration in carbohydrates was recognized and exploited by the Giese group. Thus, although the 2-deoxyglycosyl phosphates were too unstable to be isolated, they could be coupled *in situ* to various acceptors to give 2-deoxy disaccharides or nucleosides such as **175**.²¹⁶

4.4 Non-anomeric C-Radical Reduction

The radical deoxygenation of thiocarbonyl derivatives, known as the *Barton–McCombie reaction*, is one of the most widely employed methods for the deoxygenation of primary and secondary alcohols (see **Tin Hydrides and Functional Group Transformations**).^{217,218} In Scheme 25, deoxygenation of a primary *O*-trichlorophenyl thiocarbonate **176** is shown using this procedure.²¹⁹ The well-known and effective classical conditions used trialkyltin hydrides but, considering the toxicity of these tin compounds and

Scheme 24 Synthesis of 2-deoxy sugars by 1,2-ester migrations.

Scheme 25 Deoxygenation of non-anomeric alcohols. TAHP, tetraalkylammonium hypophosphite; ABCVA, 4,4'-azobis(4-cyanovalic acid); ACCN, 1,1'-azobis(cyclohexanecarbonitrile).

the unresolved difficulty of removing tin derivatives, extensive efforts have been focused in recent years in developing more environmentally benign and more easily handled alternatives, as

shown for the substrates **177–181**. For comparative purposes, the deoxygenation of xanthate **177** under the original Barton–McCombie conditions is included in Entry 1.²¹⁸ Zard reported on a

simple and efficient method by using 2-propanol as hydrogen-atom donor and DLP as radical initiator (Entry 2).²²⁰ Radicophilic cleavage of thiocarbonyl derivatives has been studied by Kim using $(\text{Bu}_4\text{N})_2\text{S}_2\text{O}_8$ and HCO_2Na as a new alkyl radical generator (Entry 3).²²¹ In a more recent work, it has been discovered that complexes of boranes and *N*-heterocyclic carbenes are competent radical hydrogen-atom donors to achieve the deoxygenation of secondary xanthates in good yields (Entry 4).²²² On other hand, Wood provided evidence that the trialkylborane/air system using water as the only hydrogen-atom source is capable of mediating the deoxygenation of xanthate esters (Entry 5).²²³ The utility of hypophosphorous compounds as cheap and ecologically acceptable replacements for triorganostannanes was first demonstrated by Barton (Entry 6).²²⁴ Recent examples include aqueous tetraalkylammonium hypophosphites (TAHPs) by Jang (Entry 7),²²⁵ and the use of dimethyl phosphite employed by Morvan.²²⁶ Several silylated 1,4-cyclohexadienes have also been examined as replacements for organotin compounds.²²⁷ The highly efficient deoxygenation of thiocarbonate **178** with silylated cyclohexadiene **182** provides a neat demonstration of the considerable synthetic potential of this methodology. Tributylgermanium hydride has also been described as a useful alternative to trialkyltin hydrides in radical reductions of thiocarbonylimidazolide **179** (Entry 9).²²⁸ A work from the Seeberger group in 2008 combines the use of TTMSS with a continuous-flow microreactor to perform deoxygenation of **179** (Entry 10) (see **Radical Chemistry by Using Flow Microreactor Technology**).²²⁹ This technique was also reported to be effective with iodinated sugars. Jang proposed an alternative method in which the deoxygenation of trifluoroacetate derivative **180** is implemented efficiently with diphenylsilane (Entry 11).²³⁰ More recently, Markó investigated the monoelectronic reduction of aromatic esters with SmI_2 , observing that the toluate moiety **181** could be a particularly useful function to achieve radical deoxygenations (Entry 12).²³¹ Also in this field, Koreeda developed a highly versatile method for the deoxygenation of alcohols starting from phosphites such as **183**.²³² Initially, an aryl radical is generated that attacks the phosphorous atom to give a phosphoranyl radical, which promotes a favored β -scission reaction producing the corresponding

C radical which should lead to the reduction product **184**.

5 CARBON–HETEROATOM BOND-FORMING PROCESSES

5.1 Carbon–Nitrogen Bond-Forming Processes

Two basic approaches to the homolytic formation of C–N bond in carbohydrate systems are available: the amination of carbon-centered radicals, and the inter- or intramolecular addition of nitrogen-centered radicals. Only a few procedures for the amination of C radicals in the carbohydrate field have been reported. The first work used the photolysis of a cobaloxime intermediate in presence of nitrous oxide as an efficient radical trap. The nitroso compound tautomerized readily to an oxime, such as **185**, which was subsequently reduced and acetylated to mannosamine **186** as a single stereoisomer (Scheme 26).²³³ Barton conveniently used diazirines as carbon radical traps.²³⁴ The carbohydrate carbon-centered radical, produced via radical exchange from the organotelluride **187**, adds to 3-(trifluoromethyl)-3-phenyldiazirine, to furnish the imine **188** in good yield. More recently, Renaud reported a practical approach for the azidation of alkyl radicals using sulfonyl azides as radical traps (see **Unusual Radical Acceptors**).²³⁵ The process involves the reaction of anomeric dithiocarbonate **189** with ethanesulfonylazide in the presence of DLP as radical initiator: the anomeric azide **190** is obtained as a single α -anomer. The azidophenylselenation of glycols, first reported by Santoyo–González *et al.*,²³⁶ Czernecki and Randriamandimby,²³⁷ and Tingoli *et al.*,²³⁸ is a powerful heterogeneous procedure that allows the one-pot preparation of phenyl 2-azido-2-deoxy-selenoglycosides such as **191** and **192**, regioselectively in high yield. This occurs when glycols are treated with (diacetoxyiodo)benzene (DIB), sodium azide, and diphenyl diselenide to generate an electrophilic azide radical which adds to the electron-rich double bond of the glycal. More recently, Nifantiev performed an improved homogeneous preparative method using trimethylsilyl azide allowing reduced reaction times and reliable scaleup.²³⁹ The reaction has also been extended to *exo*-glycals; thus D-*gluco*-hept-1-enitol

Scheme 26 Radical formation of carbon–nitrogen bonds. dmgH, dimethylglyoxime monoanion.

derivative **193** under the same conditions afforded C-glycoside **194** as a single diastereoisomer.⁷⁷ The CAN-mediated azidonitration of glycals of Lemieux and Ratcliffe provides another efficient method for the introduction of the azide group at C-2.⁸² We have devoted some attention to the 1,5- or 1,6-HAT promoted by N radicals, reporting the synthesis of different pyrrolidines and piperidines in carbohydrate systems.^{240–243} As a representative example, a suitably protected amine

195²⁴⁰ reacts with hypervalent iodine reagents in the presence of iodine to generate an N radical, which triggers the 1,5-HAT reaction to give the 7-oxa-2-azabicyclo[2.2.1]heptane system **196** after one-electron oxidation and cyclization of the amine group onto the oxocarbenium ion intermediate. Next, this work was extended to the HAT promoted by amidyl radicals generated from **197**, showing that there is an O- and N-ambident nucleophilic reactivity of the amide group.²⁴³ This reactivity

depends on the electrophilicity of the oxocarbenium ion intermediate modulated by tuning the electron-withdrawing ability of the substituents at C-5 to trigger the reaction specifically to give spiro-lactams **198** or spiro-lactones **199**.

5.2 Carbon–Phosphorus Bond-Forming Processes

The addition of phosphorus-centered radicals to olefins on a carbohydrate skeleton was first reported by Whistler in 1968.²⁴⁴ The photochemically initiated reaction of phenylphosphine with alkene **200** afforded, after oxidation under the reaction conditions, the phosphine oxide **201** (Scheme 27). *C*-Glycosides with difluoromethylene phosphonates and phosphonothioates as anomeric tethers such as **203** have been prepared by Motherwell²⁴⁵ starting from *exo*-glycal **202**. The required phosphonyl or thiophosphonyl radicals were generated by *n*Bu₃SnH reduction of diethyl(phenylselenenyl)phosphonate or diethyl(phenylselenenyl)thiophosphonate, respectively, using di-*tert*-butyl peroxide as initiator. Analogously, the radical addition of diethyl phosphite to a difluorinated

exo-glycal closely related to **202** using *tert*-butylperoxypivalate as initiator has been described by Sinay.²⁴⁶ Addition of diethyl phosphite or diethyl thiophosphite, in the presence of the triethylborane/O₂ system, to the electron-rich enol-ether of tri-*O*-acetyl-*D*-glucal afforded adducts **204** (X = O or X = S, respectively) with complete regio and diastereoselectivity.²⁴⁷ Phosphonyl radicals, generated under oxidative conditions from dimethyl phosphite and CAN, added efficiently to pentopyranose, hexopyranose, and disaccharide glycals.²⁴⁸ This strategy permitted the preparation of a variety of 2-deoxy-2-phosphonate derivatives, such as **205** and **206**. The stereochemistry can be rationalized on the basis of steric interactions; the phosphonyl radical attacks preferentially anti to the substituent at C-3. Related applications of the CAN-mediated radical addition to glycals have been described in Section 2.4.^{81,82}

5.3 Carbon–Oxygen Bond-Forming Processes

Intramolecular HAT promoted by alkoxy radicals is one of the most interesting processes for the radical generation of C–O bonds. However, it is

Scheme 27 Radical formation of carbon–phosphorus bonds.

Scheme 28 Radical formation of carbon–oxygen bonds.

worth noting that the C–O bond formation does not arise directly from the radical abstraction, but by a mixed method combining a radical HAT step and an ionic cyclization (see below). In carbohydrate chemistry, Descotes²⁴⁹ launched the application of this methodology to the synthesis of spiroorthoesters by cyclization of 2-hydroxyethyl glycosides using HgO/I_2 for the generation of the hypoiodite intermediate. We have prepared spiroacetals with 1,6-dioxaspiro[4.5]decane and 1,7-dioxaspiro[5.5]undecane bicyclic structures by cyclization at the anomeric center of C-glycosides of the 4,8-anhydro-nonitol and 5,9-anhydro-decitol type, respectively, using hypervalent iodine compounds and iodine for the generation of the alkoxy radicals.^{250,251} Chatgililoglu has also used this reagent for the preparation of anomeric spironucleotides.²⁵² Apart from the anomeric center, some other positions of the carbohydrate

skeleton have also been functionalized. For example, we have described that the alkoxy radical generated from C-glycoside **207** abstracts exclusively the hydrogen atom at C-6 to give the 6,8-dioxabicyclo[3.2.1]octane **208** after oxidation of the radical to the oxocarbenium ion intermediate (Scheme 28).²⁵³ The reaction of **210** (R = Me), possessing a two-carbon tether at C-3, abstracts the hydrogen atom at C-4 through a 1,5-HAT affording exclusively **209**. Notwithstanding, the presence of an EWG at C-4 as in **210** (R = Ac) switches the reaction to a 1,6-HAT by abstraction of the C-7 hydrogen to give the 2,9-dioxabicyclo[3.3.1]nonane **211** with complete regioselectivity.²⁵⁴ Remote functionalization between the two pyranose units of a (1 $\rightarrow$ 4)-disaccharide can also be achieved under these conditions. For instance, the reaction of alcohol **212** with the DIB/ I_2 system afforded the 1,3,5-trioxocane derivative **213** through a

rare 1,8-HAT in good yield.²⁵⁵ Taking advantage of the strict conformational requirements of the HAT TS, these reactions have been used for the selective deprotection of suitably positioned benzyl²⁵⁶ and methyl ethers²⁵⁷ in the carbohydrate framework. The reaction of methyl 2,3,4-tri-*O*-methyl- β -D-galactoside to give a mixture of methylenedioxy acetal **214** and acetate **215**, which can be subsequently hydrolyzed to methyl 2,3-di-*O*-methyl- β -D-galactoside, is illustrative. Direct radical transformation of a carbon–halogen bond into a carbon–oxygen bond is possible with molecular oxygen,²⁵⁸ as depicted for iodine **216**, or TEMPO (see **Nitroxides in Synthetic Radical Chemistry**).²⁵⁹

5.4 Carbon–Sulfur/Selenium Bond-Forming Processes

The radical addition of thiols to alkenes (thiol-ene coupling or TEC), known for more than a hundred years,²⁶⁰ has recently been considered to be a thio-click process (see **Radical Thiol–X Click Chemistry**).^{261,262} In the carbohydrate field, the addition of thiyl radicals to *endo*-glycals has also been known for some time. Igarashi and Honma²⁶³ reported that the reaction of thioacetic acid with tri-*O*-acetyl-D-glucal proceeded with C-2 addition of a thioacetyl radical to give a 7:3 ratio of D-Man/D-Glc diastereomers. When the reaction is performed with ethanethiol catalyzed by CAN, a reverse addition at C-1, which finally leads to

Scheme 29 Radical formation of carbon–sulfur and carbon–selenium bonds. DPAP, 2,2-dimethoxy-2-phenylacetophenone.

2-deoxy-1-thioglycosides, has been observed. This last result seems to be more consistent with an oxocarbenium ion mechanism.²⁶⁴ The diastereoselective radical addition of thioacetic acid to *exo*-glycals of D-Glcp **217** and L-Fucp has also been described (Scheme 29).²⁶⁵ In both cases, β -C-glycoside thioacetates, such as **218**, are formed exclusively by axial radical quenching. A number of α -D-GalpNAc thioconjugates have been prepared by reaction of 1-thio- α -D-GalpNAc derivative **219** with different olefins using AIBN as the radical initiator.²⁶⁶ A new photoinduced coupling of glucosyl and mannosyl thiols with hex-5-enopyranosides and pent-4-enofuranosides to give thiodisaccharides has been developed by Dondoni.²⁶⁷ The TEC reaction of 1-thio- β -D-glucopyranose derivative **220** with the sugar alkene **221** using 2,2-dimethoxy-2-phenylacetophenone (DPAP) as photoinitiator to give 1,6-linked *S*-disaccharide **222** is a representative example. A natural extension of the TEC reaction is the radical-mediated hydrothiolation of terminal alkynes, which serves to introduce two thiol substituents across the triple bond.²⁶⁸ This methodology has been exploited by Dondoni²⁶⁹ for the double *S*-glycosylation of cysteine-containing peptides. The one-pot, two-step sequence comprises the selective *S*-propargylation of the cysteine unit **223** followed by photoinduced radical thiol-yne coupling of 1-thio- α -D-glucopyranose (**224**). 5-Deoxy-5-seleno-D-ribose derivative **226** can be formed from benzylseleno aldehyde **225** with Sml_2 , presumably via an intramolecular homolytic substitution.²⁷⁰

5.5 Carbon–Bromine Bond-Forming Processes

The discovery that carbohydrate derivatives can be specifically brominated under free-radical conditions was made by Ferrier in 1977^{271,272} and the results obtained up to 1991 have been thoroughly reviewed by Somsák and Ferrier.²⁷³ In general, bromine, *N*-bromosuccinimide (NBS), or the $\text{KBrO}_3/\text{Na}_2\text{S}_2\text{O}_4$ system are used as brominating agents, and the radical reactions are initiated with either irradiation with visible light, benzoyl peroxide, or AIBN. The reaction occurs preferentially at the C-1 or C-5 (C-4 in furanose systems) positions of the carbohydrate skeleton, and the regioselectivity depends largely on the substituents at these positions. The reaction of

the 1,2,3,4,6-penta-*O*-benzoyl- β -D-glucopyranose (**227**) to give regio- and diastereoselectively the 5-bromine derivative **228** is illustrative (Scheme 30).²⁷⁴ The bromination of methyl D-glucopyranuronate has been studied in some detail, since the 5 α -bromo derivative obtained is an intermediate in the synthesis of methyl α -L-idopyranuronate, which is a constitutive fragment of heparine.²⁷⁵ The bromination of the α -isomer derivative **229** afforded regio- and stereoselectively the 5 α -bromo derivative **230**. Subsequently, free-radical reduction with $n\text{Bu}_3\text{SnH}$ gave a 3 : 1 ratio of L-Ido **231**/D-Glc **229** isomers.^{276,277} Interestingly, the reduction of the isomeric methyl 1,2,3,4-tetra-*O*-acetyl-5-bromo- β -D-glucopyranuronate (β -isomer of **230**) gave an inverted 1 : 2 ratio of the respective L-Ido/D-Glc isomers.²⁷⁸ Cyclic C-glycosides with an electron attractor group at the anomeric center (CN, CO_2R , or CONH_2) give regioselective bromination at this position, via a captodative stabilized radical.²⁷⁹ This situation is similar to that encountered at C-5 of the pyranuronates mentioned earlier. This methodology has been exploited by Somsák^{280,281} in the highly efficient bromination of 2,6-anhydro-aldonic acid derivatives **232** and **233**. An excellent example of the importance of the captodative effect in the regioselectivity is the bromination of the disaccharide **234**; directed by the carboxyl group, the substitution occurs exclusively at C-5 of the glucuronate moiety.²⁸² The bromination of 2,5-anhydro-3,4,6-tri-*O*-benzoyl-D-allonamide (**235**) was used by Harrington and Jung²⁸³ as a key step in the synthesis of (+)-hydantocidin **236**. During the synthesis of a number of analogs of hydantocidin, Fleet²⁸⁴ have also applied this bromination of C-glycofuranosides to 2,5-anhydro-L-talonic acid derivatives.

6 β -FRAGMENTATION PROCESSES PROMOTED BY ALKOXYL RADICALS

The alkoxy radical fragmentation (ARF) involves the reversible homolytic cleavage of a σ C–C bond located on the sugar template α, β to an O radical giving rise to a carbon-centered radical and a C=O double bond. The conditions that have been employed most frequently in the β -fragmentation reaction in carbohydrates may be broadly classified into two types: oxidative and reductive methods.²⁸⁵

Scheme 30 Radical bromination of sugars.

6.1 Fragmentation of Alkoxy Radicals under Oxidative Conditions

The formation of anomeric alkoxy radicals and its fragmentation reaction proceed smoothly in high yields using hypervalent iodine compounds, especially DIB, and iodine via the corresponding hypoiodite intermediates. In this process, the equilibrium is strongly displaced to the acyclic C radical, the anomeric carbon is transformed into a formate group, and the sugar is degraded to a lower member of the aldose series of carbohydrates. Using an electron-donor protecting group at C-2 (e.g., ether, isopropylidene), oxidation of the C radical to an oxocarbenium ion intermediate **I** is

favoured, which may be trapped intermolecularly by an acetate anion from the medium to give a mixed acetyl acetal (Scheme 31). Nevertheless, the presence of an electron-withdrawing group at C-2 (e.g., ester, carbonate, halogen, 2-deoxy carbohydrate) decreases the electron density at this position, disfavoring the oxidation and allowing the competitive trapping of the C radical **II** by an iodine atom.^{286,287} For instance, the methylether **237** gave the acetyl product **238**, whereas the benzoyl ester **239** afforded the iodide **240** in good yields. Inanaga applied this procedure to give the corresponding mixed-acetal formates which were further converted to furanose derivatives by acid-catalyzed transacetalization.²⁸⁸ We have

Scheme 31 β -Fragmentation of alkoxy radicals under oxidative conditions.

demonstrated that both inter- and intramolecular trapping of the oxocarbenium ion intermediate are possible. In the intermolecular approach, besides the acetate anion coming from the reagent, other proper nucleophiles could be added to the reaction medium, such as the thymine base shown in Scheme 31

for the synthesis of the acyclic nucleoside analog **241**.^{289,290} In recent years, we have extended this tactic to the synthesis of chiral 1,1-dihaloalditols and 1,1,1-trihaloalditols by ARF of 2-halo- or 2,2-dihalo-carbohydrate anomeric alcohols, as described for the synthesis of **242**.^{291,292} On the

other hand, the intramolecular trapping requires suitably positioned nucleophiles in the carbohydrate precursor structure. Some of these internal nucleophiles could be hydroxyl groups,^{293,294} for preparing specific furanose or pyranose forms of aldotetroses and aldopentoses; carboxyl groups²⁹⁵ giving aldo-pyranosuronic or furanosuronic acid lactones; or amine groups such as **243**,²⁹⁶ which are particularly interesting since imino sugars could be obtained in high yields. Starting from 3-azido-2,3-dideoxy-hexopyranose compounds **244**, we had the opportunity to synthesize chiral β -iodoazides **245** in good yields, which by subsequent base treatment afforded vinyl azides **246**.²⁹⁷ Analogously, the corresponding vinyl sulfones could be prepared from the oxidative fragmentation of 2,3-dideoxy-3-phenylsulfonyl-hexopyranoses.²⁹⁸ We also reported on an extension of the ARF methodology to 2-azido-2-deoxyaldoses to lead to aldonitriles such as **247** by oxidation to the α -azido cation which delivers nitriles upon loss of nitrogen.²⁹⁹

6.2 Fragmentation of Alkoxy Radicals under Reductive Conditions

The required glycopyran-1-*O*-yl or glycofuran-1-*O*-yl radicals were generated by reaction of anomeric nitrate esters such as **248** or *N*-phthalimide glycosides with *n*Bu₃SnH and AIBN giving the corresponding alditols with one carbon less (Scheme 32).³⁰⁰ Recently, Hartung highlighted the efficiency of alkoxy radical formation from 5-substituted and unsubstituted 3-alkoxy-4-methylthiazole-2(3*H*)-thiones under reductive conditions.³⁰¹ We further extended our methodology to sequential ARF-intermolecular allylation starting from *N*-phthalimide derivatives and using allyltributylstannane as radical trap to give a range of 1,2,3-trideoxyhept-1-enitol derivatives such as **249**.³⁰² Concerning non-anomeric *O*-adicals, Binkley and Koholic, who discovered nitrate esters as good sources of alkoxy radicals, described the conversion of 3-nitro-D-allofuranose

Scheme 32 β -Fragmentation of alkoxy radicals under reductive conditions.

250 into the inverted alcohol by a radical β -fragmentation-recyclization reaction as shown in Scheme 32.³⁰³ In our laboratory, a simple synthesis of L-threose by the ARF of nitrate ester and *N*-phthalimide derivatives of readily available hemiacetal **251** (*R* = H) has been developed.³⁰⁰ Along this line, Sánchez *et al.* reported the β -fragmentation of primary alkoxyl radicals from their corresponding *N*-phthalimide derivative **252**, highlighting that an internal hydrogen bond seemed to be the driving force for such a reaction.³⁰⁴

7 CONCLUSIONS

The selected examples provided in this article have hopefully demonstrated the importance of free-radical reactions in carbohydrate chemistry. The neutral reaction conditions, functional group tolerance, and experimental simplicity make these procedures highly attractive for selective transformations in this field. The predictable stereoselectivity of hexopyranos-1-yl radical reactions suggests that this may be a method of choice for the diastereoselective carbon–carbon bond formation at the anomeric center of carbohydrates. Radical chemistry provides also convenient methods for the synthesis of polyfunctionalized carbocycles by radical cyclization of acyclic carbohydrate precursors and for the introduction of heteroatoms into the sugar ring. Finally, the remote intramolecular functionalization via HAT from alkoxyl radicals and the β -fragmentation of anomeric alkoxyl radicals offer interesting new perspectives, allowing the preparation of structures that would otherwise be very difficult to synthesize.

Radical Arylations

Santiago E. Vaillard¹ and Armido Studer²

¹Laboratorio de Química Fina, Instituto de Desarrollo Tecnológico para la Industria Química (INTEC), Santa Fe, Argentina and ²Department of Chemistry, Organisch-Chemisches Institut, Westfälische Wilhelms-Universität Münster, Münster, Germany

1 INTRODUCTION

Substitution reactions are one of the most useful transformations in organic chemistry. In aromatic systems, the mechanism of the substitution process depends on the nature of the substrate and reagent as well as on the reaction conditions applied. In this regard, substitutions involving radicals are usually performed under mild and neutral conditions, and it is noteworthy that many functional groups are tolerated. Moreover, many different solvents can be used in radical chemistry; even water is tolerated to conduct synthetically important radical transformations. These reasons, together with the fact that many different functional groups can be used as radical sources, make radical reactions particularly suitable and attractive for arylation of a wide range of compounds. Radical arylations can be achieved by the $S_{RN}1$ reaction, by homolytic aromatic substitution, or by reaction of aryl radicals with different radical acceptors. In this article, we focus on the latter two approaches and present a short overview on some relevant transformations involving aryl radicals. $S_{RN}1$ -type homolytic aromatic substitutions are discussed in **The $S_{RN}1$ Reaction** and homolytic substitutions at the main-group elements are covered in **Intramolecular Homolytic Substitutions in Synthesis**.

Owing to space limitations, a comprehensive overview on homolytic aromatic substitutions

cannot be given here; for further information, the reader is referred to some recent reviews on this topic.^{1–3}

2 HOMOLYTIC AROMATIC SUBSTITUTION REACTIONS

2.1 Intramolecular Homolytic Aromatic Substitution Reactions

2.1.1 Arylation Using Nucleophilic C-Centered Radicals

Intramolecular homolytic substitution reactions of reactive aryl radicals with arenes are known for more than a century.⁴ This and some other related processes, nowadays referred to as *the Pschorr reaction*, can be used for efficient preparation of biaryl compounds. Aryl radicals obtained by treatment of aryl diazonium salts with Cu(I) salts are intramolecularly trapped with an arene moiety to give, after oxidation, cyclic biaryls with excellent regioselectivity. Other protocols for conducting these reactions use photochemical, thermal,^{5,6} or electrochemical⁷ generation of reactive aryl radicals. Moreover, various one-electron donors other than Cu(I) salts, such as Ti(III)⁸ and Fe(II)⁹ salts, as well as tetrathiafulvalene¹⁰ and iodide ions¹¹ can also be used to trigger these reactions.¹² The

Pschorr reaction has been widely used for the synthesis of several natural products and bioactive compounds. For example, in the key step of the synthesis of the pigments hipposudoric acid **3** and norhipposudoric acid **4**, a modified Pschorr reaction of diazonium salt **1** to fluorenone **2** was used (1).¹³

An interesting application of the Pschorr reaction was reported by Guo for the synthesis of DNA-photocleaving reagent **11** (Scheme 1).¹⁴ The intramolecular homolytic substitution of naphthyl radical **6**, which is readily generated from diazonium compound **5**, afforded a mixture of five- and six-membered heterocyclic compounds **9** and **10** (ratio **9** : **10** = 86 : 14). Isomer **10** was formed via a 1,5-H shift in aryl radical **6** to give **7** and subsequent

Detailed^{2–4} and recent¹⁵ investigations on the Pschorr and related processes can be found in the literature.

Halogen abstraction reaction by the tributyltin radical ($n\text{-Bu}_3\text{Sn}^\bullet$) from aryl halides (bromides and iodides) provides aryl radicals that can be used in intramolecular homolytic substitutions. This process, which was independently discovered by Narasimhan and Aidhen¹⁶ and Togo and

Scheme 1 Synthesis of DNA photocleaver **11** applying a Pschorr reaction.

Kikuchi,¹⁷ is nowadays regarded as a powerful tool for the construction of a wide range of biaryls from readily available starting materials. These reactions usually require the use of a stoichiometric amount of *n*-tributyltin hydride (*n*-Bu₃SnH); however, protocols that use only a catalytic amount of the tin hydride have also been developed. To exemplify the potential of these tin-mediated reactions, the seminal work of Narasimhan on the intramolecular homolytic substitution of bromide **12** to provide **13** is presented in (2).

For more than 20 years, these tin hydride-mediated intramolecular homolytic aromatic substitutions have been intensively applied to the formation of C(sp²)–C(sp²) bonds to prepare various important biaryl compounds.^{18–27} For example, the key step in the synthesis of the natural phenanthrene **14** (confusarin) was recently achieved using an intramolecular homolytic substitution (3).²⁸

Aryl radicals can also be generated from aryl chlorides, bromides, and iodides by applying electrochemistry.²⁹ These electrochemically formed aryl radicals then readily undergo intramolecular homolytic aromatic substitutions. Moreover,

photochemistry has been applied to generate aryl radicals that subsequently cyclize onto arenes via homolytic substitution.³⁰ Heteroarenes have been shown to be good radical acceptors for these types of transformations and a variety of heterocyclic rings such as pyrroles, indoles, pyridones, imidazoles, pyridines, and benzimidazoles have been used as acceptors in intramolecular radical arylations.^{31–41}

For all tin hydride-mediated intramolecular arylations, the initial C-centered radical, which in the case of biaryl formation is an aryl radical, is

generated by halogen atom abstraction from the halide **15** by a trialkyltin radical (Scheme 2). As discussed below, the attacking radical does not need to be a reactive aryl radical. Alkyl radicals can also be used in homolytic aromatic substitutions. The C-centered radical **16** formed adds to the arene to form a rather stable cyclohexadienyl radical **17**, which is then oxidized to the targeted product **18** (Scheme 2). Noteworthy is the fact that the oxidation step has to take place under reducing tin hydride conditions. In addition, it should be pointed out that in most of the cases a stoichiometric amount (or even more) of an azoinitiator is required in order to obtain acceptable

Scheme 2 Mechanism of the homolytic aromatic substitution reaction.

yields. Although a pseudo-S_{RN}1-type mechanism was initially proposed, detailed mechanistic studies⁴² revealed that the azoinitiator is likely responsible for oxidation of the cyclohexadienyl radical **17** to arene **18**, as initially proposed by Curran and Liu.^{43,44}

Curran also showed that oxidation of **17** can be efficiently achieved by small amounts of O₂. As documented by the conversion of iodide **19** into lactam **20**, this modification on the protocol allowed reactions to be performed at room temperature under mild conditions (4). In these reactions, O₂ acts both as an initiator and also as a reagent for oxidation of the corresponding intermediate cyclohexadienyl radical of type **17**.⁴⁵ It is obvious that the suggested mechanism is also valid for vinyl and alkyl radical additions to arenes (as indicated by the general structure of the attacking radical in Scheme 2) and of course also operates on intermolecular homolytic aromatic substitutions.

(4)

Silanes, such as tris(trimethylsilyl)silane [(TMS)₃SiH] (see **Silanes as Reducing Reagents in Radical Chemistry**), can also be used as mediating

reagents to conduct homolytic aromatic substitutions. An example is shown in (4). The tin-free protocol was successfully used for preparation of various pyrazolophenanthridines **22**⁴⁶ and pyrazolopyridines (**5**).⁴⁷ The radical precursors used were obtained from readily available starting materials.

R¹ = H, OMe
R² = H, Me, OMe
R³ = H, Me, CF₃

(5)

As discussed in Scheme 2, in most cases where an aryl radical reacts with an arene, the intermediate formed cyclohexadienyl radical is further transformed to the corresponding biaryl via H transfer or oxidation/deprotonation. However, under certain conditions, the cyclohexadienyl radical can be transformed to the corresponding cyclohexadiene by either a fast reduction or fragmentation reaction. To do so, an efficient “fast” reducing reagent is necessary. Crich nicely showed that, with benzeneselenol as an additive, the intermediately formed cyclohexadienyl radical could be reduced to the corresponding cyclohexadiene.⁴⁸ Along this line, SmI₂ (see **Organic Synthesis Using Samarium Diiodide**) has also been applied to intercept the intermediate cyclohexadienyl radicals in similar reactions. An example is shown in Scheme 3. Aryl radical **24** was generated via single electron transfer (ET) from SmI₂ to aryl iodide **23**. Cyclohexadienyl radical **25**, formed by intramolecular ipso-addition of aryl radical **24** to the appropriately positioned aryl group, was reduced with SmI₂ to the corresponding allyl anion **26**. Hydrolysis during workup eventually afforded the substituted spirocyclic oxindole **27** in good yield.⁴⁹ The fast reduction of **25** suppressed a potential 1,2-acyl or 1,2-aryl migration to eventually give the typical products of a homolytic aromatic substitution.

Scheme 3 SmI₂-mediated reaction.

Scheme 4 Synthesis of spirocyclic cyclohexadienones by aryl radical additions onto arenes.

Substrates of type **28**, bearing a *para*-trityloxyaryl group as an aryl radical acceptor, showed also a different reaction outcome. As shown for the formation of spirocyclohexadienones **31b**, the cyclohexadienyl radical **30b**, generated by intramolecular aryl radical addition, underwent fast fragmentation to

biaryl formation. Of course, similar chemistry has also been applied to the synthesis of unnatural compounds that might be useful in materials science. For example, an impressive tin hydride-mediated double arylation of a diiodide was used to access the helicene compound **33**, as shown in (6).^{59,60}

afford **31b** and the highly stabilized trityl radical. Reduction of the trityl radical sustained the chain reaction (Scheme 4).⁵⁰ It was suggested that the spirocyclic intermediate **30b** might also be formed by 1,2-aryl migration from radical **30a**. Indeed, when protecting groups (PGs) such as OTBS, Me, and Bz were installed in place of the trityl group, the main products isolated were the corresponding phenanthridinones **31a** arising by cyclization onto the ortho position via **30a** in a homolytic aromatic substitution.

Products of type **31b** can also be obtained by replacing the trityloxy group OCPH₃ by an azide substituent. In these aromatic azides, the cyclohexadienyl radical obtained after initial aryl radical addition released N₂ to provide the corresponding imine. Hydrolysis eventually delivered cyclohexadienones.⁵¹ Although there are some synthetic protocols for reduction of the intermediately formed cyclohexadienyl radicals as discussed, most cyclohexadienyl radicals rearomatize to give biaryls. The “intercepted” homolytic aromatic substitutions are rare.

Many natural products can be synthesized via intramolecular homolytic substitution reactions. For example, the synthesis of *Amaryllidaceae* alkaloids,⁵² glaucine,^{53,54} cryptopleurine,⁵⁵ benzo[*c*]phenanthridine alkaloids,⁵⁶ luotonine A, (–)-conocarpan,⁵⁷ and rutercapine⁵⁸ were all successfully accomplished by applying radical

As already mentioned, vinyl radicals have also been used as reactive intermediates in homolytic aromatic substitutions.⁶¹ Vinyl radicals are readily generated by intramolecular addition of aryl radicals to triple bonds.^{62–70} Intramolecular aromatic substitution reactions with vinyl radicals have successfully been employed in domino radical reactions for the synthesis of various camptothecin derivatives^{71–74} and ellipticine.⁷⁵ An example is discussed in Scheme 5. Aryl radical **34** reacts with phenyl isonitrile in an intermolecular addition reaction to afford imidoaryl radical **35**, which after 5-*exo*-dig cyclization gives alkenyl radical **36**. The alkenyl radical reacts with the aryl moiety in a 6-*endo* cyclization to deliver, after oxidation, compound **37** (path A in Scheme 5). It has been suggested that the homolytic substitution can also occur by ipso attack to afford the spirocyclic radical **38** (path B in Scheme 1), followed by ring opening to form iminyl radical **39**, renewed ring closure, and oxidation.

With Et₃B/O₂ initiation, imidoaryl selenide **40** reacts via imidoaryl radical **41** and subsequent 5-*exo* cyclization to vinyl radical **42**. This radical then undergoes homolytic aromatic substitution to give **43** (Scheme 6). It has been suggested that the reaction likely occurs via an initial 5-*exo*-cyclization followed by a neophyl-type rearrangement (see path B in Scheme 5). Finally, tautomerization of **43** leads to ellipticine **44**.

Scheme 5 Homolytic aromatic substitution with an intermediately generated vinyl radical.

Scheme 6 Efficient synthesis of ellipticine **44** via homolytic aromatic substitution.

Acyl radicals generated from acylselenides efficiently react by homolytic substitution under standard reductive conditions.^{58,76–82} Different

in rather low yield, by arylation of the acyl radical obtained from acyl selenide **48** under tin hydride conditions (8).⁸⁴

arenes and heteroarenes can be used as radical acceptors in these processes. The successful synthesis of the calothrix derivative **47** is a nice example to document the potential of this approach (7).⁸³ Acyl radical arylation delivers ketone **46** as initial product, which undergoes fast tautomerization to **47** and which was isolated in 90% yield. Nordanaidone **49** was successfully prepared, although

Intramolecular radical addition onto arenes and heteroarenes can also be performed with primary and secondary alkyl radicals.^{85–92} Alkyl radicals in these reactions are readily generated from the corresponding alkyl halides or chalcogenides (bromides, iodides, and selenides) using *n*-Bu₃SnH as mediating reagent by applying different initiators (for an overview on radical initiators, see **Overview of Radical Initiation**). Intramolecular arylation of alkyl radicals with imidazoles, pyrroles, and pyrazoles has been studied in detail.^{58,83} As an example, the synthesis of whitasomnine **51** using readily available alkyl selenide **50** is shown in (9).

In these DLP-mediated reactions, the biologically important indole core can also be used as a radical acceptor.¹⁰² For example, this approach was successfully applied as an easy entry into (±)-mesicarpine **58**. The elegant reaction sequence to **58** starts with an intermolecular xanthate addition of **55** to olefin **56** followed by a homolytic aromatic substitution, as depicted in (11).

Along with the tin hydride-mediated arylations, electrochemical,⁹³ photochemical,^{94,95} and iodine transfer methods^{96,97} have been reported to be useful for the generation of alkyl radicals to conduct alkyl radical arylations. In addition, nucleophilic alkyl radicals generated from aldehydes with SmI₂⁹⁸ or stannyl radicals⁹⁹ also react with arenes to give intramolecular arylation products.

In a related process, the intramolecular addition of a carbamoyl radical (an N-centered radical, see **Main-Group Elements in Radical Chemistry**), generated from the corresponding carbamoyl xanthates, onto arenes was used as an attractive entry to isoindolin-1-ones.¹⁰³

Intramolecular addition of aryl radicals to olefins is another useful route for the generation of alkyl

Scheme 7 Homolytic aromatic substitution with an iminyl radical as a key step in the synthesis of neocryptolepine **62**.

radicals, which can be used as reactive intermediates for arylations.¹⁰⁴ Iminyl radicals have also been studied in intramolecular homolytic aromatic substitution reactions. These radicals can be generated by addition of a C-centered radical to a nitrile,¹⁰⁵ by intramolecular 1,5-H transfer,¹⁰⁶ or directly from the corresponding oximes^{107–109} and hydrazones.¹¹⁰ Microwave-assisted reactions of readily available aryl-carbonyl *O*-phenyl oximes of type **59** have been reported to be useful substrates for the synthesis of various heterocyclic compounds such as quinolines, phenanthridines, benzonaphthiridines, and indolopyridines.¹¹¹ The scope of these reactions is exemplified by the formal synthesis of the antimalarial compound neocryptolepine **62** in which an indolyl group was used as a radical acceptor in the arylation reaction (Scheme 7). The

iminyl radical **60**, which subsequently reacted via an intramolecular arylation to **61**, was generated by thermal N–O bond homolysis. Indole derivative **61** was then further transformed to neocryptolepine **62**.

Malacria and coworkers have recently shown that amide-iminyl radicals of type **65**, readily generated from iodide **63** via aryl radical **64** and 5-exo cyclization onto *N*-acylcyanamides, undergo intramolecular homolytic aromatic substitution via cyclohexadienyl radical **66** to give luotonine A (**67**, Scheme 8).^{41,112,113}

Along with C- and N-centered radicals as discussed, intramolecular homolytic aromatic substitution with sulfur-centered radicals has been successfully conducted for preparation of benzothiazoles.¹¹⁴

Scheme 8 Synthesis of luotonine A.

2.1.2 Arylation Using Electrophilic C-Centered Radicals

Intramolecular homolytic arylations with electrophilic radicals have been studied to a lesser extent compared to analogous reactions involving nucleophilic radicals. Most often, in these reactions electrophilic radicals have been generated by oxidation of CH acidic compounds such as dialkyl malonates or β -ketoesters with $\text{Mn}(\text{OAc})_3$ (see **Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry**).¹¹⁵ Studies on $\text{Mn}(\text{OAc})_3$ -mediated intramolecular homolytic aromatic substitution of several dialkyl malonates^{116–120} revealed that these reactions are well suited for the synthesis of five-, six-, and seven-membered fused rings.¹²¹ Arylation can also be performed on heteroarenes as radical acceptors by using this approach.¹²² Good results were obtained for formation of six-membered rings in the reaction with electron-rich and also electron-poor arenes. Hence, for six-membered systems, the “philicity” of the radical acceptor does not influence the reaction outcome to a large extent. However, for cyclizations to seven-membered rings only with electron-rich arenes as acceptors, good results were achieved for the homolytic aromatic substitution. Other oxidants such as cerium(IV) ammonium nitrate (CAN, see **Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry**),¹²³ and iron

(III) perchlorate¹²⁴ have also been used in similar transformations.

As shown by Beckwith, electrophilic C-centered radicals can also be generated by 1,5-H shift from activated C–H bonds to intermediately formed aryl radicals. An example is provided in Scheme 9. Aryl radical **69** was generated from the corresponding bromide **68** by reaction with a stannyl radical. 1,5-H transfer allowed the generation of electrophilic C-radical **70**, which eventually further reacted to oxindole **71** by an intramolecular homolytic substitution in 87% overall yield.¹²⁵ Tin-free versions of these reactions have also been developed.¹²⁶

Other routes for the generation of electrophilic C-centered radicals that have been successfully used in intramolecular arylations are (i) direct use of selenides and bromides,^{127,128} (ii) radical addition to olefins bearing electron-withdrawing groups,^{129,130} and (iii) thermal C–O bond homolysis of adequately substituted 2,2,6,6-tetramethylpiperidine-*N*-oxyl radical (TEMPO)-derived alkoxyamines (see **Nitroxides in Synthetic Radical Chemistry and Nitroxide-Mediated Polymerization and its Applications**).¹³¹ An example of this “TEMPO-approach” representing a tin-free aromatic substitution is shown in Scheme 9. Microwave irradiation of alkoxyamine **72** delivers electrophilic radical **73**, which undergoes homolytic aromatic substitution to give oxindole **74**. In this

Scheme 9 Homolytic aromatic substitution with electrophilic C radicals.

process, TEMPO acts as oxidant for the transformation of the intermediately formed cyclohexadienyl radical to the arene.

Recently, Perry and Taylor^{132,133} and Jia and Kündig¹³⁴ independently disclosed a route to oxindoles by direct C–H/Ar–H coupling in arylanilides bearing electron-withdrawing groups. These reactions were promoted by KO^{*t*}-Bu as a base and

compounds.¹³⁶ As an example, oxidative coupling of **78** to **81** is shown in (13). Electron spin resonance (ESR) studies revealed that the electrophilic bis-radical cation **79** is generated as a reactive intermediate in this process. C–C bond formation affords the dication **80**, which is subsequently deprotonated to the corresponding biaryl product **81**.

Cu(II) as a stoichiometric oxidant. Mechanistic studies revealed that these reactions proceed by an intramolecular homolytic aromatic substitution process in which the electrophilic alkyl radicals are formed by oxidation of the corresponding enolates. Different electron-withdrawing groups such as CO₂R, CN, P(O)(OR)₂, and aryl groups allowed tandem enolization/oxidation/homolytic substitution reactions to give the substituted oxindoles in good yields. As shown in (12), when *tert*-butyl carboxylates of type **75** were used as substrates, homolytic aromatic substitution (see **76**) followed by *in situ* acid-promoted decarboxylation afforded the 3-substituted oxindoles **77** with good to excellent yields.

2.1.3 Radical Aryl Migrations

Radical aryl migration reactions are of great interest in synthetic organic chemistry. In recent years, these reactions have been successfully used as key steps for the synthesis of complex natural products.¹³⁷ The 1,2-phenyl migration of neophyl radical **82** to form the tertiary radical **84** (neophyl rearrangement, (14)) was first reported more than 60 years ago¹³⁸ and since then several related processes have been published.^{139,140} For an overview on radical rearrangements, see **Radical Rearrangements: Ester-Substituted Radicals and Hydrogen Atom Migrations**. Despite numerous efforts,

MnO₂ has recently been used for direct intra- and intermolecular coupling of electron-rich aryl

the postulated intermediate radical **83** could not be spectroscopically characterized.¹⁴¹ The neophyl rearrangement is a slow process as compared

to most other radical reactions ($k = 762 \text{ s}^{-1}$ at 25°C)^{142,143} and has been widely used as a radical clock (see **Radical Kinetics and Clocks**).^{144–146}

(14)

As an example to show the potential of the neophyl-type rearrangement in synthesis, the conversion of malonates **85** to dibenz[*b,f*]oxepines **89** under oxidative conditions is shown in Scheme 10.¹⁴⁷ On the basis of mechanistic studies, it was suggested that the stabilized tertiary radical **87** is generated by one-electron oxidation of manganese carboxylate **86**. Radical **87** undergoes rearrangement to benzyl radical **88**, which after oxidative decarboxylation affords oxepine **89**.

Another recent example on the use of a 1,2-aryl migration was published by Zard and coworkers.¹⁴⁸ Radical **90**, generated from the corresponding xanthate, was allowed to react with olefin **91** (Scheme 11). The adduct radical **92** is prone to undergo 1,2-phenyl migration to provide rearranged C-radical **93**. β -Elimination of the methylsulfonyl radical eventually leads to olefin **94**.

The methylsulfonyl radical further reacts via an α -elimination to SO_2 and the methyl radical that sustains the chain.

The 1,2-aryl migration from carbon to an O-centered radical is known as *O*-neophyl-type rearrangement.^{149–153} Recent studies on cumyloxyl radicals bearing cyclopropyl or 2,2-diphenylcyclopropyl groups in the para position of the phenyl ring as radical clocks strongly suggest that arylcarbinyloxyl radicals exist in equilibrium with 1-oxaspiro[2,5]octadienyl radicals, which agrees with the proposed mechanism for the *O*-neophyl rearrangement of 1,1-diaryloxy radicals.^{154,155}

1,3-Radical aryl migrations from carbon to C-centered radicals are unknown. However, the 1,3-aryl migration from N- to C-centered radicals has been reported (radical Smiles rearrangement).^{156–160} Treatment of xanthogenate **95** with DLP in octene under reflux yielded the 1,3-aryl migration product **97** in 71% yield. Product **97** was formed via radical **96**, as depicted in Scheme 11.

The 1,4-radical aryl migration from carbon to C-centered radicals is known for more than 60 years.¹⁶¹ Although 1,4-aryl migrations are usually considered as side reactions, some synthetically useful examples have been reported in the literature.^{162–176} A 1,4-radical aryl migration was

Scheme 10 Application of a neophyl-type rearrangement in synthesis.

Scheme 11 Neophyl-type rearrangements in synthesis. DLP, dilauroylperoxide.

used as key step of an elegant synthesis of podophyllotoxin **102**. The tertiary alkyl radical **99**, generated from thionocarbonate **98**, reacts with the double bond in a 5-exo cyclization producing radical **100**. Stereoselective 1,4-aryl migration provides alkoxy radical **101**, which, after reduction and hydrolysis, affords lactone **102** in 40% yield (Scheme 12). Other sequences that use the 1,4-aryl migration from carbon to C-centered (aryl and alkyl) radicals in arylcarboxamides have been reported for the synthesis of phthalimides, biaryls, and β -arylethylamines.¹⁷²

Radical 1,5-aryl migration reactions have successfully been used for the synthesis of several biaryls.^{177,178} In addition, aryl migration from the heavier group IV elements are meanwhile well-established reactions. For example, Wilt showed that 1,4- and 1,5-phenyl migration from silicon to C-centered radicals are rather efficient processes. These studies also revealed that the migration in these systems could be a reversible process.¹⁷⁹ Similar conclusions were drawn for the 1,5-phenyl migration from carbon to Si-centered radicals.¹⁸⁰ Later, Studer extended the concept to the stereoselective 1,5-aryl migration from silicon

to C-centered radicals.¹⁸¹ For example, reaction of iodide **103** under standard tin hydride conditions provided the aryl migration product **104** in 70% yield with a 10 : 1 diastereoselectivity (Scheme 13). The cyclohexadienyl radical **105**, in which both methyl groups are oriented in pseudoequatorial positions, was suggested as an intermediate on the way to the major isomer. The analogous radical 1,4-aryl migration from silicon to C-centered radicals also occurred with excellent diastereoselectivity.¹⁸² Furthermore, this approach can also be used for the preparation of biaryls.¹⁸³ For example, reaction of bromide **106** under radical conditions followed by desilylation yielded biaryl **107** in 71% yield. As shown in Scheme 13, the same product was prepared by aryl migration from phosphorous starting with the appropriate aryl radical precursor **108**.¹⁸⁴

The radical 1,4-aryl migration from tin to alkyl radicals has also been reported.¹⁸⁵ Moreover, radical 1,4-aryl migrations from sulfur in sulfonamides to C-centered radicals have been well investigated.^{186,187} Iodides of type **111** reacted with $n\text{-Bu}_3\text{SnH}$ under radical conditions to afford arylated products **109** (Scheme 14). It was suggested that the intermediately generated primary alkyl

Scheme 12 Complex cascade reaction involving a radical 1,4-aryl migration.

Scheme 13 Radical aryl migration from silicon or phosphorous to C radicals.

Scheme 14 Radical aryl migration from sulfur to C radicals.

radicals undergo ipso attack, forming cyclohexadienyl radicals of type **110**. Rearomatization followed by reduction and extrusion of SO₂ finally gives amine **109**. Electron-rich and also electron-poor arenes can be used in these transformations as migrating aryl groups. However, products **112** arising from homolytic aromatic substitution at the ortho position were formed as by-products in these reactions. On the basis of these results, a new radical method for the synthesis of biaryls was later disclosed by Motherwell and Pennell.^{188–191} Their method utilizes the 1,4- and 1,5-aryl migration from sulfur to aryl radicals and demonstrates that readily available arylsulfonates (X = O) and arylsulfonamides (X = NMe) are suitable substrates for that process. These reactions occur via aryl radicals of type **114**, which attack the migrating aryl group at the ipso position to eventually produce the biaryls **113** via homolytic substitution. As side products, biaryls **115** deriving from the initial ortho attack were formed. However, careful selection of the migrating aryl groups allowed suppressing the formation of this side reaction.

1,4-Aryl migration from sulfur to C-centered radicals has also been used for the synthesis of 3-arylpiperidines¹⁹² and of 2-aryl propionamides.^{193,194} Studer used the radical aryl migration from sulfur in sulfonates to secondary C radicals for stereoselective C(sp²)–C(sp³) bond formation.¹⁹⁵ Various aryl groups were transferred with high diastereoselectivities and moderate to good yields, as shown for the transformation of arylsulfonates **116** to the corresponding alcohols **117**. Analogous aryl migrations in sulfonamides turned out to be far less efficient.¹⁹⁶ The same group recently studied atroposelective radical aryl migrations in sulfonates **118** for the formation of axially chiral biaryls (**15**).¹⁹⁷ Radical precursors were prepared from readily available starting materials. Products were obtained in good yields with moderate selectivities. Importantly, the diastereoisomeric biaryls **119** and **120** were readily separated by SiO₂ column chromatography. Cyclohexadienyl radicals of type **121** were proposed as reactive intermediates in these atroposelective radical arylations.

can intermolecularly react with benzene, affording a σ complex **122**, which can readily be oxidized to cation **123** (16). The phenylation product **124** is eventually formed by deprotonation of cation **123**. Under non-oxidizing conditions, cyclohexadienyl radical **122** is rather long-lived and can dimerize to **126**, disproportionate to cyclohexadiene **125** and arene **124**, or give directly arene **124** by H-atom abstraction from intermediate **122**.

Because reactions of nucleophilic alkyl radicals with non-activated arenes are slow, many side reactions efficiently compete with the targeted homolytic substitution process. Therefore, application of this type of arylation in synthesis is limited. For example, the rate constant for the addition of the *tert*-butyl radical to benzene at 79 °C is $3.8 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$,²⁰⁴ which is clearly at the lower edge of a useful radical reaction. As a consequence of the slow radical addition, the attacking radical undergoes various side reactions such as rearrangement, dimerization, disproportionation, as well as halogen- and hydrogen-atom abstractions. The reactivity of the homolytic substitution product toward alkyl radicals is only slightly lower than

As shown in Scheme 2 for cyclizing arylations (intramolecular variant), nucleophilic alkyl radicals

that of benzene, and therefore overalkylation is an additional problem. Homolytic substitution with benzene derivatives bearing different substituents has been studied in detail. Unfortunately, in most cases low regioselectivities are obtained in the intermolecular homolytic substitution of unactivated substituted benzenes with alkyl radicals.²⁰⁵ However, high selectivities can be achieved in the reaction of nucleophilic alkyl radicals with benzene derivatives bearing electron-withdrawing groups as radical acceptors. Good selectivities were also noted for heteroarenes such as thiophene, furan, and thiazole as radical acceptors.

The intermolecular homolytic aromatic substitution using aryl radicals under reductive conditions has also been studied. In order to obtain acceptable yields, in most cases, the use of a large excess of the arene is required. In practice, arene acceptors in these arylations are used as a solvent. For example, *n*-Bu₃SnH-mediated arylation of imidazole²⁰⁶ and pyridine²⁰⁷ with aryl iodides as starting materials have been accomplished. Curran showed that aryl radical addition to benzene occurs with high yields by using (TMS)₃SiH (see **Silanes as Reducing Reagents in Radical Chemistry**) as a reducing reagent and aryl iodides as radical precursors in the presence of O₂ and pyridine at room temperature. For example, biphenyl **127** was obtained in excellent yield following this method with 4-iodoanisole as a

radical precursor (Scheme 15).⁴³ At higher temperature and in the absence of O₂ and pyridine, lower yields were obtained in that arylation reaction.²⁰⁸

Aryl radicals generated by the oxidation of aryl hydrazines with Mn(OAc)₃ (see **Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry**) react with arenes used as solvents to provide the corresponding homolytic substitution products. An example of such a transformation is presented in Scheme 15 in which the hydrazine hydrochloride **128** reacted with furan or thiofuran under oxidative conditions to afford acceptable yields of biaryls **129a** and **129b**.²⁰⁹ In a related process, aryl radicals, obtained upon oxidation of aryl boronic acids with manganese triacetate, reacted under microwave heating with arenes and heteroarenes to give the corresponding biaryls with good yields and excellent regioselectivities. As examples, reaction of phenylboronic acid with furan or thiofuran to give **130a** or **130b**, respectively, is presented in the scheme. It is noteworthy that electron-poor nitrogen heterocycles are suitable substrates for these oxidative arylations.²¹⁰

The KO^t-Bu-promoted radical arylation of electron-deficient nitrogen heterocycles has recently been studied. In this process, aryl iodides react with arenes under microwave heating yielding biaryls with excellent yields, including pyridine, pyrazine, and quinoxaline biaryl compounds.²¹¹ Although the mechanism of this interesting reaction is not clear yet, the homolytic aromatic substitution and the S_{RN}1 mechanism were suggested as the most probable reaction pathways.

Aryl radicals generated by the treatment of aryl diazonium salts with Ti(III) chloride efficiently react by a S_{RN}1-type process (see **The S_{RN}1 Reaction**) with anilines, phenols, ethers, and furans as radical acceptors.^{212,213} These reactions are of broad scope and usually give acceptable yields and regioselectivities. Notably, these biaryl syntheses have been successfully applied for the preparation of interesting natural products.

Protonated heteroaromatic compounds are electron-deficient substrates that react regioselectively with nucleophilic alkyl radicals yielding the corresponding homolytic substitution products (Minisci Reaction).^{214,215} With *p*-substituted pyridine derivatives, homolytic substitution occurred perfectly regioselective at the 2-position. Protonation is important to increase the reactivity and also the selectivity. Indeed, the same arylation

Scheme 16 Relative rates for the radical arylation of protonated pyridines with alkyl radicals.

on nonprotonated pyridine proceeded with low regioselectivity in low yield.

The rate of addition of a radical to a heteroarene correlates very well with the nucleophilicity of the attacking radical.²¹⁶ Electrophilic radicals such as $\cdot\text{CH}_2\text{CO}_2\text{H}$, $\cdot\text{CH}_2\text{CN}$, and $\cdot\text{CH}_2\text{NO}_2$ do not react with protonated pyridines. For a given nucleophilic radical, the reactivity toward homolytic substitution strongly depends on the electrophilicity of the arene. The highest rate constants were observed for the addition to the electron-deficient 4-cyanopyridinium salts **131** to give after oxidation-substituted pyridines **132** (Scheme 16). These heteroarene alkylations with protonated pyridines bearing electron-donating groups, such as a methoxy group in para-position, are up to 3.5×10^5 times slower.^{209,217} Reactivity trends indicate that polar effects are very important in these homolytic substitution reactions. In the transition state, charge is transferred from the nucleophilic radical (electron donor) to the pyridinium salt (electron acceptor).^{218,219} Frontier molecular orbital (FMO) theory²²⁰ has been used to explain the reactivity differences observed upon variation of the substituents at the pyridium salts. Furthermore, FMO can also be used to explain the regioselectivity observed in aromatic substitution reactions. The lowest unoccupied molecular orbital (LUMO) of the substituted pyridinium ions has the highest

coefficients at the carbon atoms at positions 2 and 4,²²¹ and the main orbital interaction is between the singly occupied molecular orbital SOMO of the incoming nucleophilic radical and the LUMO of the protonated heteroarene. Since the 4-position in the substrates shown in Scheme 16 is blocked, addition should regioselectively occur at position 2 of the arene ring. As expected, for unsubstituted pyridinium ions nucleophilic addition occurs at positions 2 and 4.²²² The Minisci reaction has been used for alkylation of several heteroarenes including lepidine, pyrazine, quinoline, and quinoxaline.^{223–229}

Studer recently reported on the oxidative homocoupling of aryl Grignard reagents with TEMPO (see **Nitroxides in Synthetic Radical Chemistry**) as an oxidant. The mechanism of that reaction is not fully understood. It is likely that TEMPO radicals react with arylmagnesium bromides to afford Mg-complexed aryl radicals that react with the aryl-Mg derivative either intra- or intermolecularly to give biaryl radical anions, which are further oxidized under the reaction conditions to the corresponding biaryls. Products were isolated with excellent yields (17).²³⁰

2.2.2 Arylation with Electrophilic C-Centered Radicals

The first report on a homolytic aromatic substitution reaction by using electrophilic C-centered radicals was published about 40 years ago. In the presence of $\text{Pb}(\text{OAc})_4$ ²³¹ or $\text{Mn}(\text{OAc})_3$,^{232,233} toluene reacted with acetic acid to give a regioisomeric mixture of tolylacetic acids besides several side products. Reactions occur via oxidation of acetic acid with the Pb or Mn salt to generate the $\cdot\text{CH}_2\text{COOH}$ radical, which then adds to toluene to give the corresponding cyclohexadienyl radical that is readily oxidized under these conditions. It was later shown that the electrophilic enoyl radical deriving from acetone can be generated by oxidation of acetone with $\text{Mn}(\text{OAc})_3$. Reaction with substituted

arenes affords the arylation products as a mixture of regioisomers.^{234,235} The outcome of the reaction depends on the nucleophilicity of the arene substrate. As expected for a reaction with an electrophilic C radical, better results were obtained with electron-rich arenes. In analogy, nitromethylation of electron-rich arenes was achieved by oxidation of nitromethane in the presence of an arene.²³⁶ $\text{Mn}(\text{OAc})_3$ -mediated oxidative C-radical generation is a general process that works for methylene derivatives bearing α -electron-withdrawing groups capable of increasing the acidity of the methylene protons (see **Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry**). In these processes, the most typical radical precursors are dialkylmalonates.^{237–243} A nice example documenting the potential of this arylation approach is depicted in (18). In the first step, dimethylmalonyl radical reacts in an intermolecular homolytic aromatic substitution highly regioselective at the 2-position of the indole core in **133** to give 2,3-disubstituted indole **134**. Renewed oxidative C-radical generation with $\text{Mn}(\text{OAc})_3$ and intramolecular homolytic aromatic substitution provided **135** in 83% yield.^{244,245} CAN has also been

used as oxidation reagent in intermolecular aromatic malonylations.^{235,236,246,247}

Recently, an efficient photoredox-mediated direct C–H arylation of indoles, pyrroles, and furans has been accomplished.²⁴⁸ An example of an indole alkylation is shown in Scheme 17. $\text{Ru}(\text{bpy})_3^+$ (1 mol%) in the presence of diethyl bromomalonate provides after ET the malonyl radical **136** along with the oxidized $\text{Ru}(\text{II})$ complex. This malonyl radical then undergoes homolytic aromatic substitution at the 2-position of *N*-methyl indole to give **137** in a good yield. The $\text{Ru}(\text{bpy})_3^{2+}$ complex generated can be excited by visible light to become an oxidant that reacts with triethylamine via an ET process to regenerate the $\text{Ru}(\text{bpy})_3^+$ complex closing the catalytic cycle.

Baciocchi and Byers showed that α -iodoesters, α -iodomalonates, and α -iodocarbonitriles can be used as radical precursors for the homolytic arylation of heteroarenes.^{249–255} Importantly, perfluoroalkylation of arenes can be performed by using perfluoroalkyl iodides as radical precursors. For example, radical trifluoromethylation of pyrrole with CF_3I and $\text{FeSO}_4/\text{H}_2\text{O}_2$ in dimethylsulfoxide (DMSO) occurred with excellent yield, as shown in (19) for formation of pyrrole derivative **138**.²⁵⁶

Scheme 17 Radical indole malonylation by a photocatalytic approach.

Scheme 18 Radical pyrrole alkylations.

(19)

Electrophilic C-centered radicals that can be used in intermolecular homolytic substitutions were also generated from xanthates by xanthogenate transfer reactions (see **Xanthates and Related Derivatives as Radical Precursors**).^{257–260} As an example, a radical alkylation of *N*-methyl pyrrole **141** is shown in Scheme 18. DLP delivers an alkyl radical $R^\bullet$ upon heating, which then adds to xanthate **139** to provide after fragmentation the electrophilic radical **140**. Regioselective addition of radical **140** to the pyrrole derivative generates **142**, which via H transfer to radical $R^\bullet$ eventually gives substituted indole **143**. It was later shown that similar reactions can be performed using $\text{Et}_3\text{B}/\text{FeSO}_4$ as a mediator,²⁵⁴ as exemplified in the scheme for the formation of bisubstituted pyrrole **146** starting with pyrrole **144** and xanthogenate **145**.

The role of the Fe(II) salt in this reaction is not fully understood. It has been suggested that it may act as the Fe(III) source, which should facilitate oxidation (aromatization) of the adduct radical. It is noteworthy that only three equivalents of the arene were necessary to obtain a good yield. As mentioned above, intermolecular homolytic substitutions often use the radical acceptor as a solvent or co-solvent.

Baran *et al.* demonstrated that electrophilic C-centered radicals, generated by oxidation of Li-enolates with Fe(III) and Cu(II) salts, react with indoles and pyrroles to give arylated heterocycles with excellent yields (see **Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry**).^{261–263} For example, Cu(II)-mediated oxidation of the Li-enolate **148**, which is readily generated by deprotonation of (*R*)-carvone (**147**), in the presence of indole gave arylation product **149** in 53% yield as a single diastereoisomer (20). This type of radical arylation was successfully used as key step in the synthesis of hepalindoles, (*S*)-ketorolac, (+)-ambiguine, acremoauxin A, and ozanin 3.²⁶⁴

Heteroatom-centered electrophilic radicals can also be used in homolytic aromatic substitutions. For example, dialkyl aminyl radical cations react efficiently with arenes yielding aniline derivatives. N-centered radical cations can readily be generated from the corresponding *N*-chloroamines by using catalytic amounts of metal salts, such as those of Fe(III), Cu(I), Ti(III), and Cr(III). As expected, these amination reactions work best with electron-rich arenes such as phenol and aryl ethers as radical acceptors. By using mono-substituted benzene derivatives as acceptors, amination occurs nonselectively and a mixture of ortho and para (major product) arylation products is obtained.²¹⁴ Thiocyanate radicals, obtained upon treatment of ammonium thiocyanide with Mn(OAc)₃, react with indoles and anilines affording the corresponding homolytic substitution products with excellent yields and regioselectivities.^{265,266}

2.2.3 Intermolecular Ipso Substitutions

Compared to the aforementioned methods, the intermolecular ipso substitution reaction has received little attention in organic synthesis.^{267,268} This ipso substitution occurs only in selected cases, most often nucleophilic radicals in combination with electrophilic arenes. In addition, the group to be replaced should be small to allow ipso attack, and, in addition, must behave as a good radical leaving group. Taking into account that the leaving group increases the steric hindrance at the ipso position, very often the radical attack occurs at the cine position in such systems. Therefore, ipso attack and also intermolecular cine homolytic substitution is usually observed in these reactions. In fact, in most cases the latter process is the preferred reaction pathway. For example, thiophene **150** reacted with the adamantyl (Ad•) radical to afford a 45% yield of the ipso product **152**, whereas the same reaction with the methyl radical yielded exclusively the homolytic substitution product **151** (21).

With the nucleophilic adamantyl radical, regioselectivity of the attack is controlled by polar effects. In contrast to methyl radicals, where polar effects are less pronounced, the stability of the intermediate σ complex is responsible for the regioselectivity of the initial addition step. Along this line, a change in the regioselectivity was also noted in the reaction of 1,3,5-trinitrobenzene with nucleophilic C radicals by switching from the adamantyl to the methyl radical.²⁶⁹

Radical arylation of para-substituted nitrobenzenes (*p*-X-C₆H₄NO₂) with nucleophilic 1-adamantyl radicals works only for electron-poor arenes. For nitrobenzenes bearing electron-donating substituents at the para position (X = OMe, H, and Me), ipso substitution products were not identified, whereas good yields of alkylidenation products (45–60%) were achieved with nitrobenzenes bearing electron-withdrawing groups at the para position (X = NO₂, CN, SO₂R, CO₂R, CHO).²⁷⁰

The effect of the nature of the leaving group on the ipso substitution with the 1-adamantyl radical was studied for reaction of various benzothiazole derivatives **153** to give **154** (22).²⁷¹ As expected, the best result was achieved with the arene bearing the nitro group (95%, X = NO₂). Good yields of ipso substitution were also obtained with the phenylsulfonyl, phenylsulfinyl, and acyl-substituted benzothiazoles (80%, X = SO₂Ph; 80%, X = SPh; 60%, X = CO₂Me). Halides,²⁷² methylsulfonyl, and methoxy turned out to be not good leaving groups for these ipso substitution reactions. Ipso substitutions in which the phenylsulfonyl radical acts as leaving group have been used for the synthesis of various stannylated heterocycles.²⁷³

3 ARYLATION USING ARYL RADICALS

3.1 Additions onto Olefins: Meerwein Arylation and Related Reactions

The Cu(I)-catalyzed reaction of aryldiazonium salts with olefins (Meerwein arylation) is a powerful and well-established method for arylation of various

reaction mixture.^{277,278} Alternatively, the reaction can be started with a Cu(I) salt. ET reaction from the Cu(I) species (CuX) to the aryldiazonium salt affords CuX₂ and the corresponding aryl radical, which then adds to the double bond providing the adduct radical **155**. Halide abstraction of radical **155** from CuX₂ provides the arylated product **166** and CuX which propagates the chain reaction. Arylated olefin **157** is eventually formed by an ionic HX elimination.

olefins.^{274,275} Good results were obtained for radical acceptors bearing electron-withdrawing groups such as carbonyl, cyano, aryl, and alkenyl. Depending on the nature of olefin and diazonium salt, the reaction can afford either the oxidized product **157** or the atom-transfer product **156** (23).²⁷⁶ In the Meerwein arylation, the catalytically active Cu(I) species is generated from a Cu(II) salt by reduction either with the solvent or with the impurities in the

Various radical acceptors, such as nonconjugated alkenes, acetylenes, styrene derivatives, α,β -unsaturated ketones, α,β -unsaturated aldehydes, α,β -unsaturated acids, quinones, conjugated dienes, and ene-yne have been arylated under Meerwein conditions. As an example to document the scope of the reaction, an indole synthesis that uses a Meerwein arylation as the key step is presented in Scheme 19. Radical addition of

Scheme 19 Indole synthesis using a Meerwein arylation.

substituted nitrophenyl diazonium chlorides to vinyl bromide under typical Meerwein conditions provided chlorides **158**. Reduction of the nitro group followed by cyclization afforded the corresponding indoles **159**. Tetra-substituted indoles **160** were obtained with moderate yields by following the same synthetic strategy.²⁷⁹ Other heteroarenes, such as quinolones,²⁸⁰ benzothiophenes,²⁸¹ and benzylthiazoline-2,4-diones^{282,283} can also be obtained by applying the Meerwein reaction.

Aryltriazenes **162** react with ZnI_2 to give aryl radicals, which in the presence of acrylonitrile derivatives undergo 1,4-addition. The adduct radicals are then iodinated to afford products of an aryliodination.²⁸⁶ Along with acrylonitriles, α, β -unsaturated ketones have been used as radical acceptors for this arylation. For example, by using 3-fluorobutenone as radical acceptor, α -fluoro- α -iodo- β -arylated ketones **163** were obtained in moderate to good yields (25).²⁸⁷

Other one-electron reductants are also suitable to mediate the Meerwein arylation. For example, it has been shown that Ti(III) chloride can be used for efficient generation of aryl radicals from diazonium salts.²⁸⁴ Noteworthy is the fact that a metal-free variant of the Meerwein arylation has been developed and applied for multikilogram preparation of α -arylmethyl ketones **161** (24).²⁸⁵ Although the mechanistic details on this process are unknown, an $\text{S}_{\text{RN}}1$ -type reaction (see **The $\text{S}_{\text{RN}}1$ Reaction**) seems to be feasible.

Allylation and vinylation of aryl radicals generated from diazonium salts by treatment with Fe(II) sulfate have been achieved with allyl halides (chlorides and bromides) and vinyl chlorides as aryl radical acceptors in non-chain reactions.²⁸⁸ As an example, the reaction of aryl diazonium tetrafluoroborate **164** with 2,3-dibromoprop-1-ene is presented in (26). Aryl radical **165**, which is readily formed by reduction of diazonium salt **164** with an Fe(II) salt, adds to the olefin, thereby generating the adduct radical **166**. β -Fragmentation leads to product **167**

along with a bromine radical which is then reduced by Fe(II) sulfate.

Alkyl radicals **155** generated by addition of aryl radicals onto an olefin can be trapped with various other radical acceptors. Cyanoarylation, carbodiazenylation, carboaminohydroxylation, carbohydroxylation, carboacetoxylation, carbothiolation, and carbohalogenation (Cl, Br, and I) have

Scheme 20 Radical carbodiazenylation and carboaminohydroxylation of olefins.

been disclosed.²⁸⁹ To show the potential of such processes, the carbodiazenylation (see **168**)^{290,291} and the carboaminohydroxylation²⁹² using TEMPO as radical acceptor (see **169**) are depicted in Scheme 20.

Aryl radicals generated under reductive tin hydride conditions can be trapped with activated alkenes if the intermolecular addition of the aryl radical is faster than its reduction by tin hydride. This reaction was successfully used for the synthesis of 3,4-dihydroquinolin-2-ones **172**. Reductive radical addition of various substituted ortho-iodoanilines **170** to α - β -unsaturated esters **171** afforded β -arylated esters, which further reacted by cyclization to lactams **172** (27).²⁹³

3.2 Aryl Radical Cyclizations

Ring-closure reactions using aryl radicals are useful processes for the synthesis of cyclic and heterocyclic compounds such as benzofurans, chromans, indanes, indolines, and tetrahydroquinolines, among others.^{294–296} The synthetic strategy used in these cases involves generation of an aryl radical, which then cyclizes, mostly in a 5-*exo* or 6-*exo*-trig process, to provide an alkyl radical that can further react via different pathways (Scheme 21). The intermediate radical **174**, generated after ring closure of aryl radical **173**, can be reduced with a suitable hydrogen donor to give **176** (pathway A), or react with a

Scheme 21 Radical cyclization using aryl radicals.

nucleophile affording **177** ($\text{S}_{\text{RN}}1$ reaction, pathway C), or react with a radical acceptor to provide after reduction products of type **175** (pathway B).

Aryl halides (bromides and iodides) as well as aryl diazonium salts can be used as aryl radical sources in these reactions. For example, aryl diazonium tetrafluoroborates were shown to be excellent substrates for the synthesis of substituted dihydrobenzofurans and related products.^{297,298} Along with the typical processes using tin hydrides, aryl radical formation can also be achieved by ET to the aryl halides or diazonium salts in a process closely related the well-known Sandmeyer reaction.^{299,300}

Although various environmentally benign hydrogen donors,^{301,302} such as TMS_3SiH (see **Silanes as Reducing Reagents in Radical Chemistry**) and *N*-ethyl piperidine hypophosphite, can be employed to mediate the chain reaction, $n\text{-Bu}_3\text{SnH}$ turns out to be the most useful reagent to conduct these cyclizations. Reductive cyclization of aryl radicals has been successfully used in natural-products synthesis. For example, ($\pm$)-vindoline **182** (key steps shown in Scheme 22), ($\pm$)-horsfiline, ($\pm$)-aspidoespermidine, and ($\pm$)-aphanorphine were prepared using a 5-exo aryl radical cyclization as the key step.^{303–306} Aryl

radical **179**, generated by iodine atom abstraction from **178**, undergoes 5-exo cyclization, affording the secondary alkyl radical **180**. Addition onto the azide group followed by N_2 elimination provides aminyl radical **181**, which is finally reduced to amine **182**.

To further illustrate the scope of aryl radical cyclizations in the field of natural-products synthesis, the key step of the synthesis of the antileukemic alkaloid (–)-cephalotaxine **187** is presented in Scheme 23. An elegant 7-endo/5-endo tandem radical cyclization afforded the (–)-cephalotaxine core in 32% yield under standard reductive radical conditions.³⁰⁷ Reaction of $n\text{-Bu}_3\text{Sn}^{\bullet}$ with bromide **183** affords aryl radical **184**, which undergoes a 7-endo-type cyclization to give **185**, which then further cyclizes to **186**. Tin hydride reduction eventually leads to the core structure of the natural product.

Unsaturated C–heteroatom bonds can also be used as aryl radical acceptors in radical ring-closure reactions. For example, an intramolecular aryl radical amination involving an imine as radical acceptor has been used as the key step in the synthesis of the ABC tricyclic core of ambiguine G.^{308,309}

Scheme 22 Radical cascade reaction initiated by an aryl radical cyclization.

Scheme 23 Cascade radical cyclization using aryl radicals.

Aryl radicals can also be generated starting with the corresponding aryl iodides by one-electron reduction with SmI_2 (see **Organic Synthesis Using Samarium Diiodide**). A radical/polar crossover reaction of aryl iodides adequately substituted at the ortho position with a cyclobutenyl group was used as the key step in the synthesis of penitrems **191** (see 28). Reaction of aryl

iodide **188** with SmI_2 gives the corresponding aryl radical, which undergoes fast 6-exo cyclization affording alkyl radical **189**. Reduction (radical polar crossover) of **189** provides the intermediate organosamarium compound **190**, which can be trapped with acetone to give after hydrolysis penitrem building blocks of type **191**.³¹⁰

In related work, a radical/polar crossover reaction starting with an aryl halide applying hexamethylditin as nonreductive radical mediator together with Et_3Al and oxaziridine as traps was used as the key step in the synthesis of (–)-acutumine.^{311–313}

Atropisomers of *N*-substituted *o*-iodoacrylamides such as **192** and structurally related carbamates are configurationally stable at room temperature. These compounds show a high barrier (about 20–30 kcal mol^{–1}) for racemization. Curran showed that it is possible to transfer the axial chirality of enantioenriched axially chiral aryl iodides into centrochirality by a 5-exo cyclization under standard reductive conditions (see **193**, (29)). In this reaction, the 5-exo cyclization occurs faster than racemization of the intermediately formed axially chiral aryl radical. This has been shown for several examples. Transfer of chirality in these reactions usually lies around 90%.^{314–316}

Intramolecular homolytic substitution reaction of aryl radicals at group VI heteroatoms (S, Se, and Te) has been intensively used for the synthesis of heterocyclic compounds (see **Intramolecular Homolytic Substitutions in Synthesis**). For example, aryl radicals **195** readily obtained from aryl iodides **194** under reductive conditions undergo homolytic substitution at sulfur to provide benzothiophenes **196**, as shown in Scheme 24.³¹⁷ These reactions are efficiently only if the leaving radical $\text{R}^\bullet$ is stabilized. Among other applications,

Scheme 24 Intramolecular homolytic substitution at sulfur with aryl radicals.

this approach has been used for selective deoxygenation of the 6-hydroxymethyl group in mannose derivatives.^{318,319} Different fused benzosultines and cyclic sulfinamides **198** can be prepared with good yields from halides **197** using an intramolecular homolytic substitution at the sulfur atom.³²⁰ These reactions allowed the synthesis of biaryl sulfinates in acceptable yields.³²¹ It has also been demonstrated that the leaving group R can be a phosphorus-centered radical.^{322,323}

Moreover, selenides **199** react under reductive radical conditions via a homolytic substitution at selenium to give cyclic selenium derivatives **200**, which upon water elimination provide selenophenes **201** with excellent yields (30).^{324,325} In a similar way, Te-containing heterocyclic compounds have been prepared.³²⁶

of $\text{Mn}(\text{OAc})_3$ to give phosphonates with good yields and good regioselectivities. Phosphonation of benzene derivatives was achieved with a $\text{Mn}(\text{II})/\text{Co}(\text{II})/\text{O}_2$ redox couple and dialkyl phosphites as P-radical precursors.^{327,328} It has also been demonstrated that phenyl compounds substituted with electron-withdrawing and electron-donating groups are good substrates for that phosphonation reaction. Phosphonation of benzonitrile and of 1,3-benzodioxole with diethyl phosphite to give phosphonates **202** and **203** is depicted in Scheme 25.^{329,330}

The homolytic substitution at trivalent phosphorous has recently been disclosed as a new alternative for the formation of P–C bonds. It was shown that tetraphenylbisphosphane ($\text{X} = \text{PPh}_2$) reacts under standard radical conditions with aryl radicals, which

3.3 Phosphonation and Borylation Reactions

Radical phosphonation of arenes and heteroarenes can be achieved by addition of P-centered radicals to arenes under oxidative conditions. For example, activated furans, pyrroles, and thiazoles react with dialkylphosphates in the presence

are generated from aryl iodides **204**, affording after oxidation the corresponding aryldiphenylphosphane oxides or sulfides **205** depending on the oxidant used (Scheme 26).³³¹ Very recently, P_4 (white phosphorous) was shown to efficiently react with aryl radicals to form the corresponding triarylphosphines.³³²

Scheme 25 Radical phosphonation with dialkyl phosphites under oxidative conditions.

Scheme 26 Aryl radical phosphonylation with phosphines.

Readily available trimethylstannyldiphenylphosphane (X = SnMe₃) was also used as a highly efficient radical acceptor for the formation of triarylphosphanes. Various aryl iodides **204** were reacted with Me₃SnPPh₂ to give, after oxidation, aryl diphenylphosphane oxides **205** in good yields.³³³ Addition of an aryl radical to Me₃SnPPh₂

formed from the intermediately generated diazonium salt reacts with B₂pin₂ in a formal homolytic substitution at boron (see **Boron in Radical Chemistry**) to afford boronate **209** in good yield (31).³³⁵ Notably, no metal catalysts were required to conduct these reactions.

was reported to occur at near-diffusion-controlled rate. This was nicely documented by stereospecific trapping of axially chiral aryl radicals, as documented for the transformation of aryl iodide **206** to phosphine oxide **207**.³³⁴

Recently, it was shown that *in situ* generated aryl diazonium salts (from anilines **208**) react with bispinacol borane (B₂pin₂) under radical conditions to afford pinacol boronates as valuable synthetic intermediates. It was suggested that the aryl radical

4 CONCLUSIONS

Important initial work on radical arylation appeared decades ago. These pioneering studies have paved the way to modern radical arylation chemistry. In particular, the better knowledge on kinetic data has allowed planning complex cascade processes comprising radical arylation reactions. Radical arylations are meanwhile also used in complex

natural product synthesis as nicely documented by the selected examples in this article. Despite these recent efforts, a great deal of qualitative and quantitative work remains to be done, especially in the area of stereoselective radical arylations. To conclude, we consider radical chemistry as a highly useful, promising, and important method that nicely complements ionic- and transition-metal-mediated arylation reactions. Many groups are currently engaged in this field and therefore interesting new developments can be expected in the future.

Electrochemically Initiated Radical Reactions

Martin A. Bohn, Anna Paul and Gerhard Hilt

Fachbereich Chemie, Hans-Meerwein-Straße, Philipps-Universität Marburg, Marburg, Germany

1 INTRODUCTION

Electrochemical transformations can, in principle, be considered. “Green Chemistry” because oxidation and reduction reactions are initiated by electron transfer from the substrate to the electrode or vice versa.¹ Therefore, the redox process is not associated with an additional reagent that has to be added in stoichiometric amounts and, consequently, the spent redox reagent does not have to be removed. These reagents are often toxic transition-metal complexes, the avoidance of which is most favorable from an environmental standpoint. In addition, electrochemical reactions can be controlled by the current passed through the solution through the current density at the electrode surface (galvanostatic conditions), or the applied redox potential which can be controlled in a three-electrode setup utilizing a reference electrode as internal standard. Another factor that controls the reaction is whether the electrochemical reaction is performed in an undivided cell or the anode and cathode compartments are separated by a diaphragm. In general, the less complex the electrochemical setup, the easier it is for nonelectrochemists to reproduce such transformations. In the simplest setup, two electrodes are immersed in the solution in a beaker-type cell and power is supplied by a commercial battery. The choice of the electrode materials, solvents, and supporting electrolyte also play an important role, and specific choices might be needed for optimal

results. Finally, the redox process can be performed directly at the electrode surface or, in cases where the electron transfer is hindered in whatever fashion, indirect electrolysis strategies utilizing a redox catalyst (mediator) can be applied. For detailed introduction to the theory, instrumentation, and various direct and indirect electrochemical applications, the reader is directed to the several reviews and comprehensive textbooks that are available.^{2–14}

Nevertheless, electrochemical conversions have an enormous advantage in that the redox potential can be adjusted to the needs of the individual starting material so that even small differences in the redox potential of the functional groups can be differentiated. Accordingly, electron-rich materials can be converted into radical cations upon abstraction of an electron at the anode, while electron-deficient starting materials can be reduced at the cathode to the corresponding radical anions. Once these radical cation/anion intermediates are formed near the electrode surface, in the so-called Helmholtz layer, either a follow-up reaction will occur or in some cases the intermediates undergo further redox processes to generate the corresponding cations or anions, respectively. In this article, we focus on the chemistry associated with radical cations or radical anions, as well as neutral radical species. Of particular interest are those electrochemical transformations published in the time frame from circa 1997 until 2010 that have generated new carbon–carbon bonds or led to the introduction of functional groups.

2 ANODIC PROCESSES

2.1 Intramolecular Anodic Coupling of Electron-Rich Double Bonds to Nucleophiles

Anodic electrochemical transformations have proven to be an effective method for the oxidation of electron-rich functional groups such as enol ethers **1**. Thereby, the reactivity of the enol ether **1** is altered and reactions are initiated under umpolung of the initial reactivity. The oxidation of the enol ether **1** by one-electron oxidation generates a radical cation intermediate such as **2**, which can be trapped with a nucleophile in an intermolecular fashion to form carbon–heteroatom bonds or carbon–carbon bonds (Scheme 1). This transformation affords cyclic intermediates after the bond formation process such as **3**, and a subsequent second oxidation step occurs to generate cationic intermediates such as **4** which are quenched by the solvent (YH) to obtain the final product **5**.

Such anodic processes have been initiated by the oxidation of enol ethers, N,O- or S,S-ketene acetals, and electron-rich aromatic rings. Simple olefins, enol ethers, allyl- and vinylsilanes, electron-rich aryl rings, alcohols, amides, and sulfonamides have been explored as internal nucleophiles for the formation of carbon–heteroatom and carbon–carbon bonds.^{15,16}

Scheme 1 Intramolecular cyclization by electrochemical umpolung of the starting material.

Scheme 2 Tetrahydrofuran synthesis by electrochemical oxidation of an alcohol bearing enol ether.

2.2 Oxidation of Enol Ethers

Recent applications of the electrochemical oxidation of enol ethers under current-controlled conditions to the corresponding radical cation intermediates have been reported by Moeller and coworkers. This versatile method was used for the synthesis of various carbocyclic systems either as studies in methodology or for the diversity-oriented synthesis of new carbon–carbon bonds. Various applications of electrochemical oxidation reactions utilizing enol ethers, as an example of an oxidizable electron-rich functionality, have been described as key steps in the synthesis of natural products. Out of the many applications, a selected example of electrochemical activation of an enol ethers is shown in Scheme 2.¹⁷ The electrochemical oxidation is performed on a reticulated vitreous carbon (RVC) electrode at relatively low current (8 mA), and a total amount of 2.2 F mol⁻¹ of electricity is passed through the solution.

The synthesis of C-glycosides was accomplished from enol ethers such as **6** in a current-controlled electrolysis to afford **7** in good yields as a mixture of diastereomers (Scheme 2). Nevertheless, the stereochemistry of the substrate and the choice of the protecting groups (PGs) applied play important roles, which have not been solved for all combinations.

The electrochemical oxidation of enol ethers was also applied in cases where an allyl silane was utilized to react as the electrophilic component.¹⁶ It became obvious that the choice of silyl PGs

Scheme 3 Cyclopentane synthesis by electrochemical oxidation of an allylsilane-bearing enol ether.

Scheme 4 Diastereoselectivity of the radical cation cyclization of polysubstituted starting materials.

on oxygen functionalities in **8** that do not directly react in the electrochemical conversion is crucial for the control of the products formed. In the case illustrated in Scheme 3, the diastereoselectivity is best controlled by a triisopropylsilyl (TIPS) PG to form **9** exclusively, while the *t*-butyldimethylsiloxy (TBDMS) PG led to the formation of the additional diastereomer **10**.

For the synthesis of bicyclic products such as **14** and **15**, the use of the racemic **11** led to the formation of only two of the possible four diastereomers. This stereocontrol is explained by reactive conformers **12** and **13**, which exhibit the lowest barrier for the desired cyclization via their corresponding radical cations (Scheme 4).¹⁸

Accordingly, the OTBDMS as well as the biologically important isopropenyl group were introduced with good diastereocontrol, as only the two trans isomers **14** and **15** could be detected.

The Moeller group also reported the use of nitrogen-based functional groups as trapping agents for the intramolecular cyclization of appropriate alkenyl amines such as **16** and **18** (Scheme 5).

When the enol ether moieties in **16** or **18** were oxidized at low current densities, the cyclization led predominantly to the five-membered proline-type products such as **17** and **19**. Also, excellent results were obtained when thioenol ethers (X = S) were applied in this reaction under basic conditions.¹⁹

The deprotonation of the sulfonamides **16** and **18** proved to be of advantage for the cyclization process, reducing the tendency to eliminate methanol from the primary cyclization product but also enabling the equilibrium between **20** and **21** by single-electron transfer (SET) (Scheme 6), from which the 5-*endo*-trig-cyclization toward the product rationalizes the formation of the five-membered products **22**.

2.3 Oxidation of Ketene Dithio- and N,O-Acetals

The anodic oxidation of ketene dithioacetals was investigated by Moeller for the synthesis of new carbon–carbon bonds when two electron-rich olefins

Scheme 5 Pyrrolidine formation by electrochemical oxidation of an amine-bearing electron-rich olefins.

Scheme 6 Mechanism of the radical-cation-initiated cyclization of amine-bearing thioenol ether.

are reacted with each other. The redox potential is expected to be an important issue in these reactions. Electrochemical methods are well suited to discriminate between two functional groups that differ only marginally in their electronic nature. The potential is either controlled by applying an additional reference electrode (potentiostatic electrolysis), or the current density in galvanostatic electrolysis is set to a low value. In the latter case, the low current density at the working electrode will select the starting material (or the functional group), which has the lowest redox potential as long as the diffusion of the starting material is not the limiting factor.

For this purpose, the two ketene dithioacetals **23** and **24** were synthesized and electrolyzed on an RVC anode at a constant current of

8.0 mA until 2.2 F mol^{-1} passed through the solution (Scheme 7).²⁰ The two reactions gave excellent results in terms of chemical yields, and the five- and six-membered rings were formed in the absence of the all-too-often-needed Thorpe–Ingold effect. It is interesting to note that the two reactions gave different types of diastereomers upon cyclization.

While the five-membered ring product **24a** gave the trans isomer, the cyclization to the cyclohexane derivative **24b** produced the cis isomer exclusively. This finding is in strong contrast to earlier reports concerning coupling reactions of two enol–ether-type double bonds.²¹ In these cases, the corresponding cyclization products were formed in a nearly 1:1 ratio of the cis/trans isomers. Moeller also reported the trapping of the radical cation generated from the oxidation of the

Scheme 7 Cyclization of a ketene dithio-acetal-bearing enol ether.

Scheme 8 Tetrahydrofuran synthesis of an alcohol-bearing ketene dithio-acetal.

Scheme 9 Cyclopentane synthesis of an allylsilane-bearing ketene dithio-acetal.

ketene dithioacetal subunit by oxygen nucleophiles. In these cases, tetrahydrofuran (THF) as well as tetrahydropyran derivatives²² were obtained in excellent yields and additional substituents were well accepted for the formation of the THF derivative **25** in excellent yields as a single product (Scheme 8).²⁰

In this context, the direct formation of lactones was realized when amides were utilized as nucleophilic groups in similar cyclization reactions.²³ In addition, an intramolecular cyclization utilizing an allyl silane functionality could be performed for the formation of a new carbon–carbon bond as well, and product **26** was generated in acceptable 55% yield as a mixture of diastereomers (Scheme 9).²⁰

In a very interesting cross-experiment, Moeller described the cyclization of the two ketene dithioacetals **27** and **29** (Scheme 10).²⁴ Ketene dithioacetal **27** gave the desired bicyclic product **28** with a good yield of 76% and an acceptable diastereoselectivity trans:cis = 5 : 1. The radical-type cyclization is not hindered by the steric bulkiness on the carbon bearing the radical functionality. On the other hand, the corresponding regioisomeric starting material **29** did not result in an oxidative cyclization. In this case, the steric hindrance of the internal carbon of the olefin being attacked by the radical has a strong effect on cyclization.

Scheme 10 Cross experiments for cyclization reactions of ketene dithio-acetal-bearing enol ethers.

Scheme 11 Diastereoselective formation of tetrahydrofurans for the synthesis of (+)-nemorensic acid.

Moeller also noted that these cyclization reactions were dependent on the nature of the trapping group. An alkene will react as a “radical-like” nucleophile with the radical cation. When alcohol nucleophiles are used, the observed behavior is different. In these cases, the radical cation intermediates originating either from the oxidation of a ketene dithioacetal or from the oxidation of an alkyl enol ether exhibit “cation-like” reactivity.

This observation eventually led to the design of a ketene dithioacetal starting material which was used for the synthesis of (+)-nemorensic acid (**33**). In this case, the starting material **30** was converted under oxidative conditions in an undivided cell at a constant current of 8.0 mA using 2.0 F mol⁻¹ (Scheme 11).²⁵

In the key step of the synthesis, the alcohol group trapped the radical cation intermediate **34**, while the allyl group in **30** did not react but remained available as a masked carboxylic acid functionality. The two diastereomers utilized for the electrochemical reaction were transformed with excellent stereocontrol via the transition state **34** to the desired products **31**, while **32** was formed from an analogous epimeric transition state. Finally, the natural product **33** was obtained from **31** in three more steps realizing the synthesis of (+)-nemorensic acid in only 11 steps, with the electrochemical conversion as key transformation.

Another interesting application concerning ketene N,O-acetals was the anodic oxidation reaction observed when an intramolecular allyl

trimethylsilane subunit was utilized as the radical acceptor.²⁶ A comparison of different cyclization precursors led to the conclusion that the presence of a single additional methyl substituent such as in the starting material **35** decreased the yield dramatically compared to the pure allylic system so that only 20–30% of **36** could be obtained (Scheme 12). When ketene N,O-acetals such as **37** were applied, good yields of up to 74% for the similar cyclization product **38a** were obtained as a nearly 1 : 1 mixture of diastereomers. The corresponding product **38b** was generated exclusively as the trans isomer in a lower yield of 57%.

Although the diastereoselectivity of this process is only moderate at best for products of type **38a**, the possibility for further optimization using (chiral) modification of the oxazolidinone substituents seems possible, opening the way to controlling the absolute stereochemistry of cyclization products of this type.

2.4 Oxidation of Electron-Rich Aromatic Rings

The electrochemical oxidation of electron-rich aromatic subunits can be used for the intramolecular cyclization of the intermediate radical cations. In particular, furan derivatives were utilized by Moeller and Wright for the synthesis of bicyclic and tricyclic derivatives.

In studies on the usefulness of this method, furan derivatives were investigated that were

Scheme 12 Comparison between cyclizations of ketene dithio-acetal or ketene N,O-acetals in electrochemically initiated cyclizations.

Scheme 13 Electrochemically initiated cyclization of enol ether-bearing furan derivatives.

functionalized with enol ethers such as **39** as well as ketene N,O-acetals such as **41** to optimize the cyclization process (Scheme 13).^{27,28} Both enol ether functional groups are well suited to act as the radical acceptor, and the radical cation generated by the electrochemical oxidation of the furan subunit initiates the cyclization. The tricyclic derivatives **40a** and **40b**, as well as the bicyclic product **42**, are generated in good yields as single isomers.

The synthesis of the tricyclic product **40** generated by the anodic oxidation of **39** at low current densities is a promising example of a transformation toward the synthesis of complex molecules. These selected examples illustrate that the electrochemical oxidation of electron-rich aromatic rings under controlled conditions utilizing low current densities (<20 mA) is a well-suited method to initiate such reactions.

Scheme 14 Electrochemically initiated cyclization of enol ether-bearing furan derivatives for the synthesis of (–)-alliacol A.

The application of the anodic oxidation of enol ethers as the key step in natural products synthesis was exemplified in the synthesis of linalool²⁹ and (–)-alliacol A (**45**).^{30,31} For the synthesis of (–)-alliacol A, the electrochemical oxidation of the intermediate **43** (Scheme 14) was used for the formation of the six-membered ring in **44** found in the natural products. The product **44** was isolated in an excellent yield of 88% over two steps and, after a number of further steps, (–)-alliacol A **45** was obtained.

This application also illustrates that electrochemical methods are well suited for activating functional groups based only on their lowest oxidation potential once current-controlled methodologies are applied. Other functional groups are not affected, as the higher redox potentials required are not reached. Once the chemoselective activation of the furan has been realized, the intramolecular cyclization is the major reaction pathway to form the desired products.

The Wright group also applied furan derivatives for the synthesis of tricyclic products utilizing silyl enol ethers as radical acceptor functionalities.

The two-step process consists of a copper-initiated 1,4-addition of a suitable Grignard reagent onto an α,β -unsaturated ketone (Scheme 15), followed by electrochemical cyclization and acidic workup to generate tricyclic products such as **46**.³² For this sequence, good yields of the desired products were also obtained when quarternary centers were formed and the ring size was altered depending on the α,β -unsaturated ketone or the Grignard reagent utilized, as shown in the additional examples.

Mechanistic studies revealed that the electrochemical transformation leads to the formation of the radical cation intermediate from the silyl enol ether functionality based on the lower redox potential of this group ($E_{1/2} = \sim 0.85$ V) compared to the furan ring system ($E_{1/2} = \sim 1.31$ V).

Interestingly, Wright also extended the application of the electrochemical generation of radical cations with the use of anisole-type starting materials. In a key investigation, **47** was generated as before by a copper-catalyzed 1,4-addition and then converted to product **48** by electrochemical oxidation in methanol (Scheme 16).³³

Scheme 15 Electrochemically initiated cyclization of enol ether-bearing furan derivatives for the synthesis of tricyclic products.

Scheme 16 Electrochemically initiated cyclization of enol ether-bearing anisole derivatives for the synthesis of tricyclic products.

Scheme 17 Cyclization of enol ether-bearing furan derivatives for the synthesis of tricyclic products containing functionalized quaternary centers.

Also, more complex quaternary-carbon-bearing derivatives such as **50a/b** were obtained when the copper-catalyzed 1,4-addition was performed with furan derivatives such as **49a/b** (Scheme 17). The electrochemical generation of the radical cation led to the desired product of type **50** in good yield.

An application of this method on a somewhat more sophisticated level of molecular complexity was reported by Trauner for the assembly of the carbocyclic skeleton of the guanacastepenes.³⁴ The polyfunctionalized starting material **51** was utilized for the electrochemical key step of the reaction sequence to afford the desired intramolecular carbon–carbon bond formation (Scheme 18). The product **52** was isolated in 70% yield via a diastereoselective cyclization and an approach toward the natural product class of tetracyclic guanacastepene derivatives could be realized.

2.5 Synthesis of Four-Membered Rings

The electrochemically initiated formation of four-membered ring systems starting from alkylidenmalonates can be realized in an undivided cell in terms of a paired electrolysis where processes at both electrodes are used for the generation of the product.³⁵ In these reactions, the cathodic reduction of the alkylidenmalonate **53** generates the radical anion intermediates **54**, which undergo radical dimerization to form the dianion intermediate **55** (Scheme 19). From here, several reaction pathways are accessible, resulting in a mixture of the products formed. Nevertheless, when the electrolysis is performed in an undivided cell with sodium bromide or sodium iodide as the supporting electrolyte, anodic oxidation of the halide generates the corresponding Hal_2 , which reacts with the dianion leading to the formation of the cyclobutane derivatives of type **56**.

Scheme 18 Electrochemical transformation as key step in the synthesis of the guanacastepenes skeleton.

Scheme 19 Cyclobutane synthesis via a paired electrolysis of Knoevenagel adducts.

Scheme 20 Mechanism of the electrocatalytic intermolecular cyclobutane formation.

On the other hand, the formation of four-membered ring systems by electrochemical oxidation of electron-rich enol ethers was realized by Chiba in an intermolecular cross-cyclization using two different starting materials.³⁶ The enol ether **57** is electrochemically oxidized on the basis of the less positive redox potential compared to the allyl benzene derivative **58** (Scheme 20). The umpolung of the reactivity of the enol ether radical cation **59** allows the reaction with the allyl benzene derivative to proceed in a regioselective fashion leading to intermediate **60**. This intermediate reacts as an oxidizing agent on the aromatic substituent to form the more stable radical cation **61** for the formation of the four-membered ring system. The back-electron transfer leading to the final product **62** takes place either on the cathode in an undivided cell or in homogeneous solution utilizing the enol ether starting material **57** as electron donor. Thereby, an electrocatalytic process can be realized in which the process is not stoichiometric in the current passed through the solution so that only a catalytic amount of electricity is sufficient to achieve complete

conversion of the starting materials under ideal circumstances.

Similar processes have been utilized in the past for the formation of four-membered ring systems with phenyl vinyl sulfones as starting materials in terms of a homo-cyclization.^{37,38} Recently, Felton described the cross-cyclization of phenyl vinyl sulfone in the presence of α,β -unsaturated ketones for the regio- and diastereoselective formation of cyclobutane derivatives such as **63** in moderate yields of up to 45% along with a number of side products (Scheme 21).³⁹

Nevertheless, in combination with a suitable second starting material, similar inter- and intramolecular cyclization reactions initiated by electrochemical oxidation of double bonds seem to be worth investigating in the future.

2.6 Synthesis of Biarylcompounds

Anodically generated radical cations of alkyl-substituted arenes such as **64** can follow two different reaction pathways.⁴⁰ Biaryl **66** is formed

Scheme 21 Intermolecular formation of a polyfunctionalized cyclobutane derivative.

Scheme 22 Reaction pathways of the anodically generated radical cation derived from alkylbenzenes.

when the radical cation **65** reacts with the starting compound (Scheme 22, path **A**), whereas deprotonation leads to a benzyl radical which undergoes an electrophilic aromatic substitution after being reoxidized to the cation generating a diphenylmethane compound **67** (path **B**). A major factor influencing this selectivity is the choice of solvent since, in nucleophilic solvents, the biaryl is generated as the main product, whereas the electrolysis in nonnucleophilic and therefore less basic solvents leads to the side-chain reaction forming diphenylmethanes of type **67**. The latter conversion is synthetically more valuable and therefore applied in industrial processes. Additional by-products, quinone-derivatives for example, can occur depending on the reaction medium. Therefore, the anodic coupling of alkyl-substituted benzenes is not the effective method for the synthesis of biaryl compounds compared to the well-established transition-metal-mediated coupling reactions.

Works of Nyberg^{41–43} in the early 1970s showed that the homo-coupling products of alkyl-substituted benzenes such as **68** and **69** can be obtained in moderate to good yields using carbon or platinum electrodes and a tetrafluoroborate as the supporting

Figure 1 Biaryls formed via anodic oxidation according to the procedure of Nyberg.

electrolyte (Figure 1). The solvents utilized for these conversions are acetonitrile or nitromethane.

The electrolysis of naphthalene and alkylnaphthalenes such as **70** in acetone–water leads to binaphthyls under similar conditions when the substrates are not substituted in 1-position; otherwise, the respective naphthoquinone **72** is formed via further oxidation of the radical intermediate to the cation **71** and a 1,2-shift of the alkyl-substituent in 1-position (Scheme 23).^{44,45}

Scheme 23 Formation of naphthoquinones after electrolysis of 1-alkyl-substituted naphthalenes.

Figure 2 Structures determined by NMR of the isolated binaphthyls (no yield given).

The conversion of 2-methylnaphthalene leads to four regioisomers of the binaphthyl, which were isolated in a 20:10:1.5:1 ratio as detected by gas chromatography-mass spectrometry (GC-MS). The structures of the two major isomers **73/74** and **75/76** obtained from the conversions of 2-methylnaphthalene and 2,3-dimethylnaphthalene were resolved using nuclear magnetic resonance (NMR) techniques (Figure 2). Since a preparative separation of the other isomers was not possible, their probable structures were derived from molecular orbital calculations whereby the most reactive positions of the substrate were determined.

The bulk electrolysis of fluoranthene **77** toward the perylene derivative **78** was accomplished by

Bard⁴⁶ to investigate the electrochemical properties and chemoluminescence of the radical cation generated from **77**. The process affords the formation of two carbon-carbon bonds of which the first one is intermolecular and the second one intramolecular. It was observed by means of cyclovoltammetry that the intramolecular bond formation is reversible and occurs very slowly; therefore, the direct synthesis of the perylene **79** was not performed electrochemically in preparative scales. The biaryl compound **78** was obtained in 24% yield and the second bond formation is afforded by a chemical oxidation agent (Scheme 24).

Phenol and its derivatives represent appropriate substrates for electrochemical conversions because of the electron-donating and therefore radical-stabilizing nature of the hydroxyl substituent. The anodic coupling is mostly carried out under basic conditions to obtain phenolate **80** as an intermediate, which is then oxidized to the phenoxy radical **81** (Scheme 25).⁴⁰ Common bases for this purpose are alkali hydroxides, Et₄NOH, or 2,6-lutidine. The phenoxy radicals form dimers either by carbon-carbon or carbon-oxygen bond formation leading to a variety of isomers when the substrate is an unsubstituted phenol. The main isomer is normally the para-para product **82**; but when this position is blocked by a substituent, the coupling reaction takes place at the ortho position to form product **83** (Scheme 25).⁴⁰ Under convenient conditions, further oxidation to a diphenoketone species **84** takes place; therefore the desired biaryl compound **82** must be regenerated via a subsequent reduction step.

Scheme 24 Synthesis of a perylene derivative by electrolysis and chemical oxidation of fluoranthene.

Scheme 25 Reaction pathways of the phenoxy radical.

The ortho–para coupling is followed by an intramolecular Michael addition, generating the Pummerer ketone **85**. When the radical recombination toward the coupling products is slow, the phenoxy radical is further oxidized to the cation **86**, which can react with a nucleophile or form cycloaddition products.

The selectivity between carbon–carbon and carbon–oxygen coupling of the phenoxy radical is determined by the steric and electronic properties of the substituents.⁵ Investigation of the oxidation of phenols by Nonhebel⁴⁷ suggests that the minimization of repulsion between the oxygen atoms of the combining radicals plays an important role

Scheme 26 Anodic oxidation of 2,6-di-*tert*-butylphenol.

Scheme 27 Anodic homo-coupling of 4-methylguaiaicol.

for the regioselectivity. When this minimization is not possible because of bulky substituents, the carbon–oxygen coupling represents the favored pathway.

The homo-coupling of 2,6-di-*tert*-butylphenol with LiClO₄ as electrolyte in MeOH in an undivided cell (Scheme 26) was investigated by Schäfer⁴⁸ and Torii *et al.*⁴⁹ and led to diphenoquinone **87** as the major product.

For the synthesis of the desired biphenol **88** in excellent yields, the electrolysis was performed via subsequent reduction of the initially formed diphenoquinone **87** by changing the current direction in a divided cell. Another solution is a paired electrolysis consisting of the oxidation of the starting material

in the anode cell and the simultaneous reduction of the generated diphenoquinone in the cathode cell.

An unusual anodic coupling of a substituted phenol was found by Waldvogel: oxidation of 4-methylguaiaicol (**89**) employing boron-doped diamond (BDD) electrodes led to the ortho–meta coupled product **90** instead of the expected ortho coupling (Scheme 27).⁵⁰

The electrolysis was performed in hexafluoroisopropanol whose specific role has not yet been established, but in the absence of hexafluoroisopropanol the conversion does not proceed. However, the fluorinated alcohol is capable of stabilizing radicals because of its nonnucleophilic and protic nature. The reaction requires no additional base, and

Scheme 28 Mechanism of the anodic cross-coupling.

Figure 3 Hetero-coupling products of 4-methylguaiaicol and arylethers.

Scheme 29 Products of the anodic oxidation of 4,6-dimethylphenol.

generates no phenolate prior to the electron transfer at the anode. After this oxidation of **89**, the acidity of the phenol species is increased; thus deprotonation occurs immediately to the radical **91** (Scheme 28).

The following electrophilic attack takes place at the most electron-rich position of the coupling partner to form **92**. Tautomerization to **93** and a further oxidation step afford the desired product such as **94**. The reaction can also be performed as a cross-coupling of phenol **89** with several arylethers in moderate yields (Figure 3).

When 4,6-dimethylphenol was exposed to anodic oxidation by Waldvogel, the pentacyclic spirolactone **97** was generated as a single diastereomer alongside the biaryl coupling product **95** and the Pummerer ketone **96** (Scheme 29).⁵¹ The spirolactone **97** represents a trimer of the starting material formed via three dehydrodimerization steps.

As the reaction is performed in basic media, the formation of **97** begins with an electrophilic attack of the phenoxy radical **98** on the enolate of the Pummerer ketone **96** (Scheme 30). Further oxidation

Scheme 30 Proposed mechanism of spirolactone formation.

Scheme 31 Electrolysis of 2,6-dihalogenated phenols.

Scheme 32 Mechanism of the anodic coupling of 2,6-dihalogenated phenols.

generates the radical anion **99**, which undergoes cyclization to intermediate **100**. Another SET is followed by a Meerwein rearrangement, leading to spirolactone **97**.

The anodic oxidation of ortho–ortho' dihalogenated phenols accomplished by Nishiyama⁵² generates the ortho-substituted diarylether (**101**) or the biaryl compound (**102**) depending on the halogen substituent (Scheme 31). While the biaryls are obtained from diiodophenols, the analog chlorine and bromine compounds provide the diarylethers, which represent the building blocks for the isodityrosine class natural products. In case of mono-halogenated phenols, the reaction leads to the same products, but the selectivity is independent of the type of halogen atoms. The steric demand of the adjacent substituents is the only factor of consequence.⁵³

The oxidation of the dihalogenated phenol initially leads to a phenoxy radical with the unpaired electron localized either at the oxygen atom (**103a**) or one of the halogen-substituted carbons (**103b**) (Scheme 32). According to density functional theory (DFT) studies, the oxygen-localized radical resonance structure is always preferred, but the

preference is, in agreement with the experimental results, higher for the dichloro and dibromo system than for the diiodo system.⁵²

A homo-coupling of the bromine-substituted carbon-localized radical **103b** is in any case improbable because of the repulsion of the bromine atoms; therefore, the carbon–oxygen coupling pathway toward the diarylether **104** is favored. In the case of iodine, the biaryl product **105** is formed after cleavage of one halogen substituent via a nonradical mechanism.

Starting from halogenated L-tyrosine derivatives, the diarylether coupling product of the dibromo derivative **106** was obtained in 45% yield and could be converted into isodityrosine (**107**) in two steps (Scheme 33).^{54,55} By changing the halogen substituents to iodine, the same anodic oxidation created the biaryl compound **108** in 28% yield, a precursor of dityrosine **109a**, and its *N*-formylated derivative aldostatin **109b** which is an aldose reductase inhibitor.⁵²

The electrooxidative coupling of arylothers to biaryl compounds such as **111** occurs in combination of two radical cations and is more selective than the coupling of the corresponding

Scheme 33 Application of the coupling of 2,6-dihalogenated phenols for the syntheses of dityrosine-class natural products.

phenols because of the protected hydroxyl functionality which makes the side reaction toward diarylethers impossible (Scheme 34). Furthermore, the *ortho* coupling and quinone by-products are less readily formed. However, the initially formed radical cations **110** are highly sensitive to the attack of nucleophiles present in the reaction medium; hence water-free conditions are required. The conversions are usually performed in dichloromethane (DCM) or acetonitrile in combination with trifluoroacetic acid (TFA) to lower the nucleophilicity. The over-oxidized dicationic biaryl species **112** is more stable under acid conditions, thus avoiding further reactions to unwanted by-products.

A frequently used electrolyte is Bu₄NBF₄ as in the synthesis of biaryls such as **113a** starting from 1,2-dimethoxybenzene by Parker (Scheme 35). The respective coupling of *ortho*-bromanisole to **113b** was accomplished under the same conditions.⁵⁶

A methoxy-substituted triphenylene derivative **114** was obtained in 60% yield by mixed electrolysis of anisole and veratrol (Scheme 36).⁵⁷

Functionalized triphenylene cores, which represent receptors for the binding of alkylated oxopurines⁵⁸ such as caffeine, were synthesized by Waldvogel under similar conditions (Scheme 37).⁵⁹ The coupling of chiral spiroketals derived from catechol affords two diastereomers of the triphenylene

Scheme 34 Biaryl synthesis via anodic coupling of arylenes.

Scheme 40 Synthesis of isoquinolines and benzazepines.

product **115**. These electron-rich donors are able to host electron-deficient guest molecules showing C_3 symmetry.⁶⁰ An intramolecular electrochemical coupling reaction for the synthesis of alkyl-bridged biphenyls of type **116** was accomplished by Parker (Scheme 38).^{61–63} The formation of a diradical

species **117** is necessary for this conversion to proceed toward the intramolecular product **118**; otherwise, the dimer of the substrate will be formed.

The six-membered ring resulting from the diphenylethane **116** is further oxidized to the corresponding phenanthrene **118** at higher potentials (Scheme 38).⁶¹ Under typical conditions, five-, seven-, and eight-membered rings (**119**) derived from methoxylated diphenylalkenes were obtained in excellent yields (Scheme 39).

Isoquinolines and benzazepines of types **122** and **123** were obtained via intramolecular cyclization at the anode by Schäfer (Scheme 40).⁶⁴ The conversion of the alkyl-linked aryl enaminones **120/121** was performed in MeOH with NaClO_4 as the supporting electrolyte. The products **122/123** could be isolated in good yields and represent building blocks in the syntheses of alkaloid natural products.

The electrochemical reaction of arylamines toward biaryl compounds of type **125** proceeds in analogy to the conversion of arylethers starting with the generation of a radical cation **124** (Scheme 41). The synthesis of the benzidines **125** resulting from carbon–carbon coupling (path A) is accompanied by the formation of diphenylamines **126** (path B) when utilizing primary or secondary arylamines.

The selectivity strongly depends on steric factors since the biaryl product of type **125** is favored in the presence of bulky alkyl substituents R, but the product ratio is also determined by substrate concentration, current density, and pH of the solution.⁶⁵ In dilute solutions at high current densities and low pH values, the benzidine compound is the major product, whereas the opposite conditions predominantly lead to the diphenylamine. The electrolysis is usually carried out in acetonitrile with Et_4NClO_4 as the supporting electrolyte.⁴⁰ Under these conditions, the

Scheme 41 Electrochemical conversion of dialkylanilines.

Scheme 42 Homo-coupling of aniline derivatives toward biaryl compounds.

homo-coupling of *N,N*-dimethylaniline was accomplished by Hand and Nelson⁶⁶ in moderate to good yields to produce **127**, while the respective coupling of diphenylamine yielding 80% of benzidine **128** was performed by Cauquis (Scheme 42).⁶⁷

An oxidation–reduction sequence for the synthesis of 10,10'-bisvindoline (**131**) was presented by Tabakovic (Scheme 43).⁶⁸ The synthesis was carried out in a divided cell in MeCN with LiClO₄ and additional TFA in the anode cell, where at first the bis-indole alkaloid vindoline **129** was oxidized

to the radical cation **130a/b**. This intermediate is stabilized by several resonance structures and dimerizes to the product **131**. On account of further oxidation to the dication **132**, changing the current direction after full conversion is required to obtain the desired product in 60% yield.

The application of unsubstituted indoles in anodic oxidation leads to polymers linked at 2 and 3 positions. Polyindoles represent electroconductive materials, which have evoked interest in the field of sensors. Investigations by Berlin *et al.*⁶⁹ have shown the initial formation of a 3,3'-coupled dimer **133** for the oxidation of 1-methylindole in acetonitrile. Further electrolysis generates the tetramer **134** (Scheme 44).

Sessler recently succeeded in synthesizing cyclo[8]pyrrole **138** electrochemically from tetraethyldipyrrole **135** (Scheme 45).⁷⁰ They found that the conversion strongly depends on the size of counter anion of the ammonium salt applied as the supporting electrolyte. The yield ranges from 0% with tetrabutylammoniumfluoride (TBAF) and almost 70% with tetrabutylammoniumdihydrogensulfate (TBAHSO₄). This is explained by templating effects of the anion during the polypyrrole formation, which leads to stabilization of the

Scheme 43 Dimerization of vindoline.

Scheme 44 Electrochemical generation of an indole tetramer.

Scheme 45 Synthesis of cyclo[8]pyrrole.

linear intermediates such as **136** and **137**. However, when the anion is too basic, deprotonation might occur leading to side-product formation.

The conversion starts with the anodic generation of a radical cation (**136**), which undergoes dimerization to **137** after being deprotonated. Further oxidation and deprotonation leads to the tetramer and its cyclization to cyclo[8]pyrrole **138**.

2.7 Kolbe Electrolysis

The dimerization of two sp^3 -carbon-centered radicals generated by electrochemical one-electron

oxidation of the homologous carboxylic acid is generally known as *Kolbe synthesis* (Scheme 46).

The short-lived intermediate acyloxy radicals **139** rapidly decarboxylate, leading to aliphatic radicals of type **140**. If two free radicals combine, the desired Kolbe dimer is obtained. The most commonly encountered side reaction results from a second oxidation process, resulting in the formation of the corresponding carbocation **141**, which, being itself an unstable intermediate, generally reacts with any present nucleophile. This process is known as *non-Kolbe synthesis* or the *Hofer–Moest reaction*.

The conditions leading to the preference of Kolbe synthesis over Hofer–Moest chemistry are well

Scheme 46 Electrochemical generation of acyloxy radicals **139** with subsequent decarboxylation giving sp^3 carbon radicals **140** and their reactions.

understood: polar/protic solvents (mainly methanol), platinum anodic electrode, weakly acidic pH (easily achieved by the addition of up to 30 mol% of alkali alkoxides, thus regulating pH and generating the supporting electrolytes *in situ*), and high current densities are the conditions commonly used.

The success of the Kolbe dimerization depends strongly on the substrate applied. Substituents in α -position, which stabilize cations, lead to Hofer–Moest products via **144** (Scheme 47). As

such, tertiary (and to a lesser extent secondary) carboxylic as well as α -hydroxy or α -amino acids are generally not convertible to the required radical species **140**. Electron-withdrawing substituents in the α -position, on the other hand, strongly favor the formation of radical species **146** and thus lead to the desired dimeric Kolbe products. Notable exceptions are α -nitrilo acids, which give radical **148** upon oxidation. Dimerization can proceed through both of the shown mesomeric forms, leading to a

Scheme 47 Effect of the substrate substitution pattern on the outcome of the electrolysis of carboxylic acids (EWG: electron-withdrawing group).

Scheme 48 Reaction of two different substrates under Kolbe conditions.

Scheme 49 Example of separable mixtures of dimers of orthogonally protected diaminodicarboxylic acids based on the applied protecting groups.

mixture of products **149** (Ritter-type reactivity) and **150**.

Yields for Kolbe dimerizations of substrates with hindering α -substituents are generally below 25–30%, although some new approaches offer the possibility of improvement (sono-emulsions for example).⁷¹

The rather indiscriminating reactivity pattern of the radical intermediates **140** and **151** leads to statistical mixtures of products (**152**, **153**, and **142**) when two different acids are applied (Scheme 48). Unless the acids in question are of greatly different polarity and/or molecular structure, separation of these mixtures is usually not readily attainable. However, when one of the acids (usually the less expensive one) is used in excess, the formation of one of the symmetrical dimers (**142** in Scheme 48) is suppressed, greatly simplifying the purification of the desired unsymmetrical mixed Kolbe dimer. Some work has been carried out utilizing differently

protected glutamic and aspartic acids in the synthesis of orthogonally protected diaminodicarboxylic acids where both starting materials are present in 1 : 1 ratio (Scheme 49).⁷²

While no solution to the low yields of this scenario is presented (12–16% of the desired mixed dimers **154** are obtained), utilizing Boc (*tert*-butoxycarbonyl)/EtTos (ethyl tolyl sulfone) on one glutamic acid and Cbz (carboxybenzyl)/Bn (benzyl) on the other generally leads to mixtures that are separable by column chromatography based on the greatly different polarity of the protected diaminodicarboxylic acids (Scheme 49).

The applicability of the Kolbe reaction in the formation of numerous substance classes (1, ω -diesters, long-chain hydrocarbons, etc.)⁷³ and natural products^{74–76} has a long and proven track record, which has been discussed elsewhere. Two recent works, however, have extended the range of applicability of this venerable reaction.

Scheme 50 Radical cyclization initiated by Kolbe electrolysis.

Scheme 51 Effect of an electron-withdrawing group (EWG) on the radical cyclization of ϵ -unsaturated carboxylic acids.

Building on the pioneering work of Schäfer^{77–79} regarding the radical cyclization of ϵ -(**155**, **159** in Scheme 50) and ζ -unsaturated carboxylic acids to five- and six-membered rings, respectively, Lebreux has shown that the yield of the cyclization product is greatly increased, compared to the almost 1 : 1 ratio of cyclized (**160**) to linear (**161**) product obtained for a terminal olefin, when the double bond is electron deficient (Scheme 50).⁸⁰

Both the 5-*exo*-trig and 6-*exo*-trig cyclizations, leading to cyclopentanes (**163**) and hexanes (**165**), readily occur under these conditions (Scheme 51), although the 6-*exo*-trig cyclization does appear to

be somewhat slower, as a small amount of linear product **166** was obtained.

The nature of the electron-withdrawing group (EWG) is not unimportant: unbranched α,β -unsaturated esters smoothly give the product in excellent yield (**167**, Figure 4), while α -methyl unsaturated esters already give a mixture of cyclized (**170**) and cyclization/Hofer–Moest tandem product derived from an intermediate presumably analogous to **157**. Nitriles predominantly lead to **168** and, while no mention of alternative products is made, it appears plausible that side reactions deriving from radical intermediates of type **148** might play

Figure 4 Products obtained from the 5-*exo*-trig cyclization presented in Scheme 51.

Scheme 52 Synthesis of tetrahydrofuran and tetrahydropyran derivatives via electrochemically initiated radical cyclizations.

a role in the lower yield. Unsaturated ketones do not appear to be substrates in this conversion, as the cathodic reduction of the α,β -double bond completely dominates (**171**, Figure 4).

The application of electron-deficient olefins and the universal use of the Thorpe–Ingold effect enable the reported increase in yields and selectivities with respect to the desired cyclization reactions.

Besides acetic acid, propanoic and isobutyric acids were also applied as co-acids, both leading to the desired products in good yields (**169** and **172** respectively, Figure 4).

Ethers of type **173** could also be applied (Scheme 52), permitting the generation of THF derivatives with a wide range of functionalities derived from various co-acids (**174a–e**). Only the

electron-poor trifluoroacetic acid proved to be unreactive (**174f**). Products of the type **175** were obtained only in poor yields, presumably because of steric congestion of the intermediate radical, as no further products were reported. Tetrahydropyran derivatives are accessible in excellent yields (**176**) when a gem-dimethyl substitution pattern is applied. Without the dimethyl moiety, the obtained yield is reduced (**177**), coupled with the generation of a further linear product **178** possibly originating in a rearrangement of either a radical or carbocationic intermediate.

The classical application of the Kolbe reaction is the dimerization of primary carboxylic acids leading to the decarboxylated dimer (refer to Scheme 46). While the reaction generally proceeds smoothly,

Scheme 53 Kolbe dimerization of primary aliphatic carboxylic acids utilizing SiO₂ gel-supported piperidine.

Scheme 54 Influence of α -heteroatoms on the outcome of the electrolysis of carboxylic acids.

yields of significantly lower than 50% are the norm.

Recent work by Fuchigami has increased the yield that can be expected for the dimerization.⁸¹ This was achieved by the application of silica-gel-bound piperidine as the base, with the resulting ammonium carboxylate pair serving as the supporting electrolyte, in methanol/acetonitrile 1:1. Interestingly, no Ritter-type side reactions derived from the attack by the generated radicals on the nitrile functionality of the co-solvent were reported.

Using this new methodology, excellent to quantitative yields were obtained in the cases that favor generation of the radical (**140**) over the cationic (**141**) intermediate (Scheme 53). Purification was reported to be greatly simplified: filtration and removal of the solvent were usually the only tasks required to allow isolation of pure product. The silica-bound piperidine proved to be recyclable; up to 10 cycles were reported without loss of activity.

The general limits of the Kolbe reaction do, however, still apply. Benzylic radical intermediates, generated from 2-aryl acetic acids, lead to the formation of a significant amount of Hofer–Moest products and thus lower yields of the desired dimer (**142d** and **142h**). The dimerization yields are

nevertheless still higher for these substrates than usually obtained when using the original procedure. Following this trend, the same authors have also reported that heteroatoms in α -position as in **179** to the newly formed radical intermediate lead exclusively to the generation of the carbocationic species, so that non-Kolbe products such as **180** are the only species observed (Scheme 54).⁸²

The higher yields obtainable with the silica-bound piperidine bring the yield into synthetically interesting ranges. Should the mixed Kolbe reaction be equally amenable to this strategy, it stands to reason that renewed attention will be directed at this venerable transformation.

Shtelman and Becker recently reported the successful synthesis of 1,2-bissilyl ethanes (**182a–c**, Scheme 55) from the corresponding α -silyl carboxylic acids (**181**, Scheme 55).⁸³ Part of the interest for this project was derived from the uncertain influence of the α -silyl group on the outcome of the Kolbe reaction. The authors note that competing electronic influences of the Si–C bonds (α/β -Si effect) might lead to unexpected results for these α -silyl acids. Should the cationic intermediate be preferred, substantially lower yields are to be expected. The results indicate that radical formation is indeed the preferred pathway, as good yields are obtained, after optimization, for the three examined silyl groups (Scheme 55).

It was found that the standard Kolbe conditions did not lead to successful conversion of the starting materials. When the amount of base (the preferred base was 3 N KOH) applied was increased to 20%, the yield responded favorably, leading the

Scheme 55 Electrochemical dimerization of α -silyl acetic acids.

authors to the conclusion that the weaker pK_a of the α -silyl acetic acids (5.22 vs 4.75) was to blame for the initial failure. Higher current densities (200–250 mA cm^{-2}), room temperature, and a 3 : 1 MeOH/MeCN mixture were further identified as optimal parameters. Electricity consumptions of over 3 F mol^{-1} were also found to be detrimental.

Kolbe electrolysis has also been used by Sugiyama and Nohira to generate P-chiral bisphosphine compounds via the intermediate P-chiral phosphinoyl carboxylic acids (Scheme 56).^{84,85} Starting from phosphine, the key racemic phosphinoyl carboxylic acid intermediate is obtained after several steps. Optical resolution by fractional crystallization using (–)-(S)-1-phenylethylamine as the resolving agent gave the desired chiral compounds (**183**). Standard Kolbe conditions permitted the synthesis of

the P-chiral bisphosphine oxides (**184**) in 60–65%, isolated yield from which the bisphosphines (**185**) were liberated by reduction with phenyl silane. The expected side products of the Kolbe reaction account for the nonquantitative yield and could be isolated, showing varying amounts of Hofer–Moest, disproportionation (where possible), and esterification products. The absolute configuration was confirmed by conversion of **185** into bisphosphine–borane complexes (**186**) and by comparing with available literature for optical rotation values. The bisphosphino ethane **185** was used as a chiral ligand, with rhodium giving chiral complexes of type **187**. This complex was tested in the hydrogenation of α -(acylamino)acrylic derivatives. The corresponding saturated compounds showed good to excellent enantiomeric excesses, proving the worth of

Scheme 56 Generation of P-chiral bisphosphino ligands with Kolbe electrolysis as the key step.

this type of P-chiral chelating ligand in asymmetric catalysis. Higher homologs of the bisphosphino compounds are also accessible.

2.8 Aminoxyl Radical-Mediated Reactions

The electrochemical generation of radicals from various precursor molecules permits the rapid and selective functionalization or defunctionalization of molecular scaffolds. Many of these processes involve radical species only transiently or as noncritical intermediates. While these reactions are in and of themselves fascinating, they do not fall under the scope of this brief overview and as such we point to the original publications themselves for those interested in further information.^{86–98}

One of these fields of work which should nonetheless be highlighted is the regeneration of reactive intermediates in the catalytic application of stable N,O radical species (see **Nitroxides in Synthetic Radical Chemistry**). This approach underlines the synthetic utility of radical chemistry in general and the unique opportunities afforded by the appropriate use of electrochemistry. TEMPO (2,2,6,6-tetramethylpiperidine-*N*-oxyl, **188**) is the most prominent of this class of stable radicals and numerous uses are known; stoichiometric quantities of this species are often required, but the addition of an oxidant to regenerate the active species **189** and thus allow catalytic turnover with regard to

TEMPO are also common. In this context, Schäfer has applied catalytic amounts of TEMPO as a mediator in the selective electrochemical oxidation of carbohydrates to the respective uronic acids.^{99,100}

TEMPO is electrochemically converted to the actual chemical oxidant: the nitrosonium cation **189**. After the target oxidation itself is carried out, hydroxylamine **190** reacts with another equivalent of **189** to regenerate TEMPO itself, thus closing the catalytic cycle. The electrochemically generated species (**189**) is not just the key oxidant but also crucial for the regeneration of the catalyst. A wide range of carbohydrates such as **191** were reacted under the reported reaction conditions, a small excerpt of which (**192–195**) is shown in Scheme 58.

A range of functionalities is tolerated, and in general the yields are good to excellent. The nitrosonium cation **189** can evidently discriminate handily between the primary and secondary hydroxy functionalities, thus permitting selective oxidation. One of the key limitations of this method is that the anomeric center must be protected.

Demizu *et al.* carried out further tests with different stable *N*-oxyl radicals, here azabi- and tricyclic systems, which owe their stability to Bredt's rule.¹⁰¹ The nitrosonium cations (equivalent to **189**, Scheme 57) were successfully applied in the oxidation of primary and secondary alcohols to aldehydes and ketones. In many cases, such as the oxidation of menthol (**196**) to **198** mediated by **197** in Scheme 59, the alternative *N*-oxyl radicals lead to significantly higher yields than TEMPO.

Scheme 57 Role of TEMPO in the electrochemical oxidation of carbohydrates.

Scheme 58 Examples of the uronic acids accessible via the TEMPO-mediated electrochemical oxidation of carbohydrates.

Scheme 59 Electrochemical oxidation of menthol mediated by azabicyclic *N*-oxyl radical **197**.

2.9 Halide-Mediated Reactions

The opening of carbocycles and subsequent derivatization of the thus obtained radical intermediates is a strategy that shows promise. Royer's group has published work on the anodic oxidation of *N*-cyanomethyloxazolidines of type **199** (Scheme 60). They have observed that, in the presence of halogenides (Cl^- and Br^-), which are presumed to act as mediators in the course of the reaction as well as the halogenating agents, a gem-dihalogenated product **200** is observed, while in the presence of water products of type **201** are obtained.¹⁰²

A general feature of these reactions is that the presence of at least traces of bromide is essential to obtain high yields and rates of reaction. The authors provide mechanistic evidence pointing toward the crucial role of the trihalogenide anions, which are generated *in situ* following electrochemical oxidation of the simple halogenides to the elemental halogens, for successful conversion of the starting material (Scheme 61). The proposed hypothesis argues that tribromide is the superior electron transfer agent and thus critical to the success of

the conversion of **202** to **207**. The bromination is believed to proceed from **204a/b** to the iminium cation **205**, which is then in equilibrium with the bicyclic intermediate **206**. Repetition of this sequence leads to the dihalogenated product **207**. Fluoride was not able to mediate the oxidation, in accordance with its high oxidation potential. The use of iodide was not reported.

When vinyl ethers are added and lithium perchlorate is used as the supporting electrolyte, the result is the expansion of the ring system to the cyclization product **208** (Scheme 62).¹⁰³ A similar mechanism is postulated, with the addition of the unsaturated ether to intermediate **209** as the key step.

2.10 Functional Group Exchange Reactions

Le Gall presented a case where the selective fragmentation of an electrochemically generated radical was exploited to deliver a valuable compound. They report that, upon anodic oxidation of *N*-substituted α -silyl piperidines of type **210** in the presence of a cyanide source, exclusive exchange of the silyl group for cyanide to generate products of type **211** is observed.¹⁰⁴

Scheme 60 Electrochemical functionalization of oxazolidines **199a-c**.

Scheme 61 Postulated mechanism for the electrochemical functionalization of **202**.

Scheme 62 Electrochemical ring expansion of oxazolidines with vinyl ethers.

Scheme 63 Exchange of silyl for nitrile functionality in piperidine derivatives (PG: protecting group).

The mechanism is postulated to proceed via a preliminary N-centered radical cation derived from **210**, which leads to exclusive fragmentation of the α -C–Si bond. This generates a secondary C-centered radical which is subjected to a second oxidation step leading to an intermediate iminium ion, which is then attacked by cyanide to yield the α -nitrile amine products of type **211**. The nitrile group always assumes an axial orientation in the piperidine ring. The authors offer an explanation based on the stereoelectronics of the intermediate iminium cation. The rationale is broadly identical with the concept of an anomeric effect as derived from carbohydrate chemistry.

A common problem when subjecting tertiary or secondary amines to anodic oxidation is the lack of specificity with respect to which the α -bond fragments to generate the iminium cation. A novel solution was presented by Yoshida's group.¹⁰⁵ They determined that the C–S bond of a N,S-acetal (**212**) functions as an electrochemically activated breaking

point (Scheme 64). The thus-derived iminium cation **215** can be subsequently derivatized by nucleophilic attack to yield product **216**.

The first step is the oxidation of the carbamate nitrogen in **212** to generate the radical cation **213**. Despite a second α -position being available for fragmentation, the α -C–S bond is selectively cleaved, freeing an S-centered radical **214** (which reacts with a second equivalent to generate a disulfide) and the electrophilic iminium cation **215**. Various carbon nucleophiles were tested, and good to excellent yields of the corresponding products of type **216** were reported.

2.11 Coupling Reactions Initiated by Anodic Oxidation

The coupling of substituted catechols (**218**) and aromatic thiols (**217**) via electrochemical oxidation of both substrates was achieved by Becker

Scheme 64 Electrochemical functionalization of α -thio carbamates with carbon nucleophiles.

Scheme 65 Oxidative electrochemical formation of thioethers.

(Scheme 65).¹⁰⁶ While the desired thioethers of type **219** were obtained in poor to acceptable yields, the products do show a relatively high degree of functionality and are reported as intermediates of interest for materials and biological applications.

Although the mechanism of this transformation has not yet been elucidated, the authors speculate that the coupling might take place via the reaction of two separate electrochemically generated radical intermediates, **220** and **221**, which then combine to give the product upon re-aromatization.

3 CATHODIC PROCESSES

3.1 Cyclizations Induced by Reduction of Carbonyl Groups

The reduction of carbonyl groups by SmI_2 is a very versatile method for the initiation of cyclization reactions of suitable starting materials utilizing 2 equiv of the reducing agent (see **Organic Synthesis Using Samarium Diiodide**). In order to reduce waste and to be able to continuously adjust the redox potential for each individual starting material, electrochemical reduction would be the method of choice. Recent applications in such cyclization reactions have been reported by Kise for the generation of mono- and bicyclic products starting from ketones and oximes. As acceptor

functionalities, imides,¹⁰⁷ indole derivatives,¹⁰⁸ and esters,¹⁰⁹ were used.

Of particular interest are those reactions that involve heteroaromatic scaffolds such as the indole derivative shown in Scheme 66.¹⁰⁸ The electrochemically initiated reaction of indole derivative **222** generates the tricyclic product **223** in good yield of 68% in an undivided cell (divided cell; 65% yield), which is comparable to the yield obtained for the chemical method utilizing SmI_2 as reductant (73%).

The electrochemical method allows the formation of the product **225** in moderate yield (46%) with three adjacent chiral carbon atoms with reasonable diastereoselectivity (Scheme 23). Interestingly, the corresponding SmI_2 -initiated reaction from **224** led to a different distribution of products. In this case, **225** was generated alongside 6% of **226**, but the tricyclic derivative **227** was also isolated and identified as yet another cyclization product.

In the case of the ester-functionalized starting material **224**, cyclic voltammetry indicated that the reduction is more likely to proceed at the

Scheme 66 Reductive cyclization of a ketone-bearing indole derivative.

Scheme 67 Comparison of the electrochemical and chemical reductive cyclization of a ketone-containing indole derivative.

Scheme 68 Reductive cyclization of a ketone-bearing alkene and alkyne derivative.

α,β -unsaturated subunit rather than at the keto functionality as in **222**. Accordingly, the reduction of the two starting materials generates radical anions at different functional groups based on the redox potential. The chemical reducing agent SmI_2 generated a mixture of products in the presence of hexamethylphosphoramide (HMPA) as cosolvent, while, in the absence of HMPA product **225** was formed in 73% yield.

Nonconjugated enones and ynones were applied by Nishiguchi for the synthesis of functionalized five- and six-membered carbo-, sulfur- and nitrogen-containing heterocycles.¹¹⁰ The electrolysis was conducted with aluminum electrodes, and the application of enones such as **228** gave the desired products **229** in moderate to good yields (Scheme 68), whereas the electrolysis of the ynone **230** gave the corresponding cyclic allylic alcohol derivatives of type **231** in good to excellent yields.

The application of ionic liquids such as 1-methoxyethyl-3-methylimidazolium mesylate (MOEMIM) as solvent and electrolyte, together with isopropanol as proton donor, was reported by Yadav in the electrochemical reduction of β -ketoesters and β -ketoamides such as **232** (Scheme 69).¹¹¹ In these cases, the β -dicarbonyl groups were substituted with an alkyl group and a 1-butenyl substituent at the α -position to suppress the formation of enolates. Accordingly, the polysubstituted products such as **233** were formed in good to excellent yields, in good to exclusive diastereoselectivities, and with excellent regioselectivities.

The electrochemical reduction of carbon–carbon double bonds can be easily achieved when electron-deficient double bonds are used as starting materials. Accordingly, educts of the Knoevenagel type have a long track of successful applications in

Scheme 69 Reductive cyclization of an alkenyl substituted 1,3-diketone in an ionic liquid.

such reactions. In the presence of *in situ* accessible nucleophiles (such as malonates), two successive carbon–carbon bond formations can be realized in a one-step procedure. Thereby, cyclopropanations of Knoevenagel-type starting materials can be realized.^{35, 112–120} The reactions are performed in alcoholic solvents utilizing a halide source as the electrochemical mediator, and, therefore, from a mechanistic point of view, such reactions are most likely initiated by an electroreductively generated alkoxide base that deprotonates the malonate-type starting material and the oxidation of the halide, initiating ionic follow-up reactions with the Knoevenagel-type materials applied.

3.2 Nickel-Mediated Reduction of Alkylhalides

Another type of functional group that is well suited for electrochemical reductions under mild conditions are alkylbromide or alkyl iodide derivatives. Being adjacent to ester functionalities, the radical anions such as **235** are stabilized and lead to cyclization reactions with unsaturated groups along the chain (Scheme 70). The electrochemical reduction of such starting materials (e.g., **234**) can be performed directly at the cathode surface with only

moderate success,¹²¹ or indirectly utilizing nickel complexes acting as mediators.^{122–125} In these latter cases, the desired cyclization product **236** could be obtained in up to quantitative yield, depending on the nickel complex used as the redox catalyst or the substituents present in the starting material.

Consecutive tandem cyclizations have been described by Toyota for the synthesis of norbornene-type structures utilizing vinylbromides such as **237** as starting material under nickel redox catalysis (Scheme 71).¹²⁶ The tandem cyclization reaction via intermediates **238/239** and **240** led predominantly to the endo-substituted norbornene product **241** in moderate yield. Alongside the norbornene products (**243**) formed from bisallyl-modified cyclic enones (**242**), spiro-bicyclic products such as **244** could also be obtained in moderate yield.

On the other hand, when additional double bonds were not present as in **245**, the formation of bicyclic compounds such as **246** via a tandem cyclization reaction sequence initiated by the reductive carbon–bromine bond cleavage was observed (Scheme 72).¹²⁷ In these cases, the Thorpe–Ingold effect seems to have promoted the cyclization; only the appropriately substituted carbocycles or furan- and pyrrolidine-derivatives were investigated.

Scheme 70 Mechanism of the indirect electrochemical nickel-mediated reductive cyclization of a halide-bearing alkyne.

Scheme 71 Mechanism of the indirect electrochemical nickel-mediated reductive tandem cyclization of a halide-bearing polyene.

Scheme 72 Mechanism of the indirect electrochemical nickel-mediated cyclopropane formation from a halide-bearing alkene.

Nickel catalysts were also used for the cleavage of the carbon–sulfur bond in thioesters, as was described by Ozaki. In these cases, the thioester functionality in **247** is easily cleaved under reductive conditions. Interestingly, this procedure can be used for the generation of the sulfur-centered radical for the synthesis of sulfur-containing heterocycles¹²⁸ as well as for the generation of acyl radicals (**248**) as shown in Scheme 73. In the latter case, the acyl radical **248** led to the formation of the corresponding ketones **249** upon intramolecular addition to a double bond and further reduction and protonation.^{129,130}

In this context, the further reduction of the sulfur-centered radical to the thiolate anion was

utilized by Ozaki for the nucleophilic ring-opening reaction of epoxides to generate 5,7-membered bicyclic sulfur-containing heterocycles in an intramolecular fashion.¹³¹

Although the application of organic electron-transfer reagents of the triarylamine type is an oxidative indirect electrochemical-initiated reaction, the methodology fits well into the context of indirect electrochemical reactions. Accordingly, triarylamines can be utilized for the electron-transfer-initiated Povarov reaction of aromatic imines with styrene derivatives and dihydrofuran via radical cation intermediates of type **251** (Scheme 74).¹³²

The reaction is very dependent on the redox potentials of the starting material **250** and the

Scheme 73 Mechanism of the indirect electrochemical nickel-mediated thioester cleavage for the synthesis of a ketone.

Scheme 74 Mechanism of the indirect electrochemical triarylamine-mediated, oxidatively induced Povarov cyclization.

styrene derivative applied. The reaction takes place only when the oxidation potential of the dienophile is appreciably lower than that of the hetero-diene **250**. Nevertheless, when the redox potentials are well chosen, the *cis* product **252** and the *trans*-configured product **253** are formed in excellent combined yield.

Inokuchi reported a cobalt-mediated method leading to cyclohexane-1,4-diones (**258**) in moderate to acceptable yields from cyclopentane-1,3-diones (**254**).¹³³ Cobaloxime was used as the cobalt source, and the electrochemical generation of a cobalt(I) species permitted the abstraction of

bromine from the substrate **254** leading to the primary radical **255** (Scheme 75). The ring-expanded cyclohexane-1,4-dione **258** is thought to result from a formal 1,2-acyl shift (**255** to **257**) via cyclopropane **256** and subsequent reduction to an enolate and protonation.

A further cobalt-mediated transformation of styrene to cyclopropyl benzene has been presented.¹³⁴ An electrochemical reduction of vitamin B₁₂ (a naturally occurring cobalt–corrin complex) was carried out to generate the reactive Co(I) complex. This reacts with DCM, leading to the chloromethyl radical, which adds to styrene. The benzylic

Scheme 75 Cobalt-mediated ring expansion of cyclopentane-1,3-diones.

radical thus generated is postulated to be further reduced, and the resulting anion should attack the chlorine-bearing carbon intramolecularly. The desired product cyclopropyl benzene was obtained in quantitative yields. No other substrates were examined, but the work does however hint at the tantalizing prospect of combining biologically derived or inspired molecules with synthetic electrochemistry.

3.3 Coupling Reactions Initiated by Reduction of Ketones

Radical anions generated via cathodic reduction processes are also viable synthetic intermediates. Gennaro and coworkers examined the reactions of radical anions **260** derived from the benzophenone and its halogenated derivatives **259** with CO_2 to afford α -hydroxy carboxylic acids such as **261** (Scheme 76).¹³⁵

Yields of the target α -hydroxy carboxylic acids were generally good to excellent; only in two cases did the yield fall below 80%. The main focus was however on the elucidation of the mechanistic aspects of this transformations. The author's proposed mechanism is outlined in Scheme 76. The reaction is initiated by the reduction of the ketone

259 to the respective ketyl anion radicals, which capture CO_2 , leading to formation of the carbonate **260**. A further reduction step leads to a carbanionic intermediate, which itself nucleophilically attacks CO_2 giving a carbonate/carboxylate intermediate that is transformed to the final α -hydroxy carboxylic acid **261** after acid workup freeing the alcohol functionality by hydrolysis of the carbonate moiety. The key to obtaining high yields, as reported, is deemed to be the presence of CO_2 , as the intermediate ketyl radical anions suffer fragmentation of the C–X/Y bonds, precluding the formation of halogenated α -hydroxy carboxylic acids of type **261**.

A relatively early report of the reductive coupling of ketones and imine-type compounds was provided by Shono *et al.*¹³⁶ Under cathodic conditions, the ketone was reduced to a ketyl radical anion (**262**) which then reacted with the imine derivative (oximes, hydrazones, and nitrones are reported as viable reaction partners) to form the α -amino alcohol compound after chemical reduction (Scheme 77). A wide variety of ketones and nitrogen-containing compounds were reacted, and some examples are presented in Scheme 77 (**266–275**).

Cyclic and acyclic ketones and oximes are suitable substrates for this conversion, with yields

Scheme 76 Reactions of halogenated benzophenones with CO_2 under reductive conditions.

Scheme 77 Reductive coupling of ketones with oximes, hydrazones, and nitrones.

generally in the good to excellent range (see compounds **266**, **267**, **269–271**). More complex ketones also react satisfactorily, as shown by the reaction of a steroidal ketone leading to **268**. Hydrazone and nitron derivatives also lead to the respective β -amino alcohol precursors **272** and **273**, although the yields are lower than in the reactions with the oxime compounds. Intramolecular cyclizations are also amenable to this methodology, as exemplified by **275**. Yields and selectivities for the cyclizations are satisfactory to good.

Initial efforts have been reported that combine many of the optimization parameters specific to electrochemical systems, thus enabling new synergistic possibilities of reaction activation. An interesting application of triple activation was reported by Compton, who applied photoactivation, ultrasound emulsification, and electrochemistry to permit a reaction previously not readily attainable.¹³⁷

3.4 Defunctionalization

Defunctionalization of aryl and alkyl halides has been reported by several groups with two broad trends being recognizable: direct defunctionalization through direct electron transfer and subsequent C–Hal bond cleavage; or activation of transition metals or complexes thereof, which then carry out the defunctionalization chemistry. Both the direct defunctionalization at various electrode materials^{138–140} and the transition-metal-mediated defunctionalization have been examined from a primarily mechanistic viewpoint, but no particular effort with a methodological/synthetic focus has been reported.^{141–144}

4 CONCLUSIONS

The generation of neutral as well as charged radical species can be performed by electrochemical

methods, as shown by many applications in the past and present. The usefulness of electrochemistry for the initiation of relevant organic transformations has been demonstrated in basic transformations such as the formation of carbon–carbon bonds as well as the formation and the cleavage of carbon–heteroatom bonds.

The use of the anode and cathode as mass-free redox reagents will always be of considerable interest in terms of effectiveness and environmental compatibility. Nevertheless, electrochemical methods are still considered as complicated and difficult to master. The examples outlined in this article illustrate that the allocation of time and resources required initially is not futile, as the pay off is most rewarding.

While fundamental questions are still being addressed, evermore sophisticated applications are being and have been developed and applied to the selective activation of functional groups in increasingly complex starting materials. The fact that research groups are willing to apply electrochemical redox processes in the synthesis of complex molecules and do so with success is a remarkable confirmation of the utility of these transformations and a sign of how far this field has developed.

Radical Chemistry by Using Flow Microreactor Technology

Takahide Fukuyama and Ilhyong Ryu

*Department of Chemistry, Graduate School of Science, Osaka Prefecture University,
Sakai, Osaka, Japan*

1 INTRODUCTION

Since the nineteenth century, the glass flask (batch reactor) has been a familiar tool used by chemists to carry out chemical reactions. Radical reactions, which generally require heat and/or light, are no exception. However, rapidly evolving microreaction technology based on tiny microchannels, typically tens to hundreds of micrometers wide and deep, has attracted increased interest because of its high potential as a reaction apparatus ideal for chemical reactions.^{1–11} A microreaction system allows the chemical reactions to take place in a very narrow space. However, when coupled with a continuous flow system, it can serve as a production tool for synthetic organic chemistry and even for the chemical manufacturing industry. The primary advantage of such a system over conventional batch reactors is the very large surface-to-volume ratios for the microchannels. As illustrated in Figure 1, tiny microchannels allow not only efficient mixing of substrates and reagents but also very rapid heat, light, and mass transfer through the walls, which potentially affects the time, yield, and selectivity of the reactions (Figure 1). In this article, the focus is on the recent advances in radical reactions using microreaction technology, with an emphasis on the ways chemical devices can contribute to better results in ordinary synthetic radical reactions.¹²

2 THERMALLY INDUCED RADICAL REACTION

Of the wide variety of radical reactions, group 14 metal hydride-mediated radical reactions are the most widely used in organic synthesis (see **Silanes as Reducing Reagents in Radical Chemistry and Tin Hydrides and Functional Group Transformations**).^{13,14} The typical reaction time found in the literature for tributyltin hydride-mediated reactions in a batch flask reaction ranges from 10 minutes to hours. Ryu and coworkers examined the tributyltin hydride-mediated radical reaction of organic halides using a stainless steel microflow reactor.¹⁵ They found that the superior thermal efficiency inherent in tiny channels allowed for the rapid execution of the tin hydride-mediated radical reduction of bromoalkanes in less than 5 minutes. Importantly, they pointed out that 2,2'-azobisisobutyronitrile (AIBN), a slowly decomposing initiator, which is frequently used in batch reactions, is not an ideal initiator in a microflow reactor, when shorter reaction time is intended. Indeed, on using radical initiators that decompose more quickly, such as V-65 and V-70, the reductions took place within 1 minute to give the reduced product in high yields (Scheme 1).

Ryu and coworkers applied the high-speed radical reaction to the gram-scale synthesis of a

Figure 1 Thermal- and photoreactions using batch and microflow reactors.

tetrahydrofuran (THF) derivative,¹⁶ which is a key intermediate for the synthesis of furofuran lignans, using a microflow system consisting of two micromixers (MiChS type- α) and a stainless steel tube reactor connected serially (Scheme 2).¹⁵ Radical cyclization took place with 1-minute residence time to give the desired methylene tetrahydrofuran. Continuous operation for 185 minutes gave 7.6 g of THF derivative without any problem (Scheme 2).

Seeberger and coworkers reported the tris(trimethylsilyl)silane (TTMSS)-mediated radical reduction¹⁴ of alkyl halides and alcohol-derived thiocarbonyl derivatives (Barton–McCombie deoxygenations)¹⁷ using a Syrris glass microreactor with a 1.0-ml heated retention unit connected with a back pressure regulator (BPR), which enabled the reaction to occur at a temperature higher than the

boiling point of a solvent.¹⁸ The BPR also works to suppress undesirable plug flow caused by N_2 generated from the radical initiator. The deoxygenation of a xanthate derived from D-galactose proceeded to give 6-deoxy-D-galactose in high yield with a 5-minute residence time (Scheme 3). They also reported that the hydrosilylation of terminal alkynes¹⁹ was faster for a microflow process. For example, a hydrosilylation reaction using the microreactor proceeded with a 5-minute residence time to give vinylsilane in good yields (Scheme 3).

Kim and coworkers developed monolithic and flexible polyimide (PI) film microreactors, which can be easily fabricated by photoablating a PI film.²⁰ The PI film microreactors are durable for many organic solvents, such as toluene, *N,N*-dimethylformamide (DMF), and

*Ten hours half-life decomposition temperature

Scheme 2 Gram-scale synthesis of a key intermediate for the synthesis of furofuran lignans.

dimethyl sulfoxide (DMSO), highly acidic conditions (2 N H_2SO_4), and reasonably high temperatures (up to 100 °C). Tributyltin hydride-mediated radical reduction and radical cyclization proceeded smoothly

with the use of a PI film reactor. In the example shown in Scheme 4, the radical cyclization product was obtained in 59% yield with 5-minute residence time at 100 °C (Scheme 4).

Scheme 3 TTMSS-mediated Barton–McCombie deoxygenation and hydrosilylation of terminal alkynes.

Scheme 4 Tributyltin hydride-mediated radical cyclization using PI-film microreactor.

Microreactor technology can be employed for gas–liquid biphasic reactions, which include radical carbonylation reactions requiring high CO gas pressure.^{21–23} Ryu and coworkers reported radical carbonylation of alkyl halides in a microflow system that is durable under pressurized carbon monoxide gas.²⁴ The microflow system consisting of a micromixer and a tube reactor, both made of stainless steel, was employed. The system was connected to a BPR to regulate and maintain

the reactor system under gas pressure. Carbon monoxide was fed into a micromixer in a controlled manner through a mass flow controller and mixed with a solution containing a substrate, a radical initiator, and a radical mediator, which was fed by a pressure-durable syringe pump (Figures 2 and 3). Using this gas/liquid flow system, radical formylation of alkyl halides proceeded well to give aldehydes in good yields (Scheme 5). Tributyltin hydride-mediated cascade carbonylation reactions

Figure 2 Microflow system available for radical carbonylation using pressurized CO.

Figure 3 Mass flow control unit for carbonylation under pressurized conditions.

leading to unsymmetrical ketones²⁵ and lactams^{26,27} were also carried out successfully using a similar microflow system.

Studer and coworkers reported on the addition of 2,2,6,6-tetramethylpiperidine 1-oxyl (TEMPO)-malonate to alkenes under heated conditions using a conventional batch reactor.^{28,29} They found that microwave irradiation effectively accelerated this thermally induced radical reaction.³⁰ However, the formation of an undesirable decarboxylation product, formed by further thermal decomposition, was not suppressed in either batch method. The Studer group and the Ryu group jointly circumvented such a side-reaction issue by the use of a microflow system.³¹ In the microflow system, a carboaminoxylation product was obtained in high yield without suffering from the formation of a

decarboxylated product, which was supposed to be derived by the thermally induced second reaction (Scheme 6). An improved product selectivity may result from the digital-like on/off switching of heating and cooling available in a microflow reaction.

Free radical polymerization is a method used widely to obtain polymers on an industrial scale, irrespective of the nature of radical polymerization (noncontrolled or living, see **Fundamentals of Controlled/Living Radical Polymerization and Radical Polymerization in Industry**). Free radical polymerization is potentially exothermic because of the fact that a σ -bond is formed at the cost of a π -bond, and, therefore, precise temperature control is required to obtain controlled polymers. Iwasaki and Yoshida³² reported free radical polymerization of butyl acrylate, benzyl methacrylate, methyl methacrylate, vinyl benzoate, and styrene using AIBN as a radical initiator. They observed that during the polymerization of butyl acrylate, benzyl methacrylate, and methyl methacrylate using microreactors, the polydispersity index (PDI, M_w/M_n) was much smaller than that obtained with a conventional macro batch reactor (Scheme 7), while no appreciable effect of the microreactor on PDI was observed for the polymerization of vinyl benzoate and styrene. Yoshida and coworkers also reported an example of large-scale production for poly(methyl methacrylate) (PMMA). Using microtube reactors of varied inner diameters (i.d. = 500 μ m, 1950 mm $\times$ 8 + i.d. = 500 μ m, 1950 mm $\times$ 8 + i.d. = 1000 μ m, 1950 mm $\times$ 8, total reactor volume = 18.4 ml), 4 kg of PMMA was synthesized by continuous operation for 1 week.³³

Scheme 5 Radical carbonylation in a microflow system.

Atom transfer radical polymerization (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**) of 2-hydroxypropyl methacrylate using a microreactor with $500\text{ }\mu\text{m} \times 600\text{ }\mu\text{m}$ microchannel was recently reported by Beers and coauthors.³⁴ Polymerization proceeded with 92% conversion and 1.21 PDI with a 2-hour residence time (Scheme 8). They also reported the synthesis of block copolymer poly(ethylene oxide)-*block*-2-hydroxypropyl methacrylate using bromo-substituted poly(ethylene oxide) as an initiator.³⁵

Serra and coworkers reported nitroxide-mediated radical polymerization (see **Nitroxide-Mediated Polymerization and its Applications**) of styrene and *n*-butyl acrylate using a microflow system.³⁶ Using 2,2,5-trimethyl-3-(1-phenylethoxy)-4-phenyl-3-azahexane as a radical initiator, a polymer with 1.20 PDI was obtained in 45% conversion with 100-minute residence time at $140\text{ }^{\circ}\text{C}$ (Scheme 9). The result was comparable to that obtained with a batch reactor. They also reported the synthesis of a poly(*n*-butyl acrylate)-*block*-poly(styrene) copolymer using serially connected microreactors.³⁷

Scheme 6 Radical carboaminoxilation of alkenes in a microflow system.

Scheme 7 Radical polymerization of benzyl methacrylate in a microflow system.

Scheme 8 Atom transfer radical polymerization in a microflow system.

The nitroxide-mediated living radical polymerization of styrene, which used a microflow reactor, was studied jointly by Studer and Ryu groups. They used nitroxyl-malonate as an initiator and propylene glycol-1-monomethyl ether-2-acetate (PGMEA) as a solvent to prevent the clogging

in the microchannels (Scheme 10). Polystyrene (PS) with 1.09 PDI was obtained in 48% conversion with a 5-hour residence time at 105 °C (Scheme 10).³⁸ Reaction at higher temperature using BPR gave PS with 87% conversion and 1.19 PDI.

Scheme 9 Nitroxide-mediated radical polymerization in a microflow system.

Scheme 10 Radical polymerization using nitroxyl-malonate in a microflow system.

3 PHOTOINDUCED RADICAL REACTIONS

Microreactors are also useful for photochemical reactions (see **Synthetic Radical Photochemistry**), since very thin channels allow efficient photo-irradiation (Figure 1).^{39,40} Since light strength attenuates exponentially with increasing optical path length according to the Lambert–Beer law ($\log(I_0/I) = \epsilon cl$), reactions run in microflow systems would be expected to terminate in considerably short irradiation time. This has tempted

chemists to use microreactors for selective radical halogenation reactions.⁴¹ Photoinduced radical chlorination of toluene-2,4-diisocyanate using a falling-film microreactor supplied by IMM (Institut für Mikrotechnik in Mainz) with a quartz window (600- μm width, 300- μm depth, 6.6-cm length, and 32 parallel channels) and a 1000-W Xe lamp was reported by Jähnisch and coauthors.⁴² Side-chain chlorinated product 1-chloromethyl-2,4-diisocyanatobenzene was obtained in 54% yield with a 14-second residence time (Scheme 11). With

Scheme 11 Photoinduced radical chlorination using Cl_2 in a microflow system.

a longer residence time, the system suffered from the formation of unidentified byproducts.

The Ryu group demonstrated microflow photo-chlorination of cycloalkanes, using chlorine gas or sulfonyl chloride as a chlorination reagent.⁴³ Photo-chlorination of cyclohexane with chlorine gas was carried out using DNS (Dainippon Screen Mfg. Co. Ltd.) photo-microreactor composed of photo-etched stainless steel microchannel (1000-μm

width, 300-μm depth, and 2.35-m length) with covered Pyrex glass. On exposure to natural light, chlorocyclohexane was obtained in 20% yield with high selectivity for single chlorination (>95%; Scheme 12). Irradiation using a 15-W black light (peak wavelength: 352 nm) was effective for chlorination of cycloalkanes, especially when sulfonyl chloride was used as a chlorinating reagent.⁴³ For example, the reaction of cycloheptane

Scheme 12 Photoinduced chlorination of cycloalkanes using Cl_2 or SO_2Cl_2 as a chlorine source in a microflow system.

Scheme 13 Photoinduced radical bromination of cycloalkanes.

with SO_2Cl_2 using a Mikroglas Dwell Device as a photo-microreactor gave mono-chlorinated cycloheptane in 87% yield with high single selectivity (>95%; Scheme 12). The use of BPR was effective in suppressing the disordered stream because of the evolution of SO_2 gas. Photoinduced radical bromination of cycloalkanes also worked well when 15-W black light and Mikroglas photo-microreactor were used. For example, bromination of cycloheptane with Br_2 proceeded smoothly to give the mono-brominated product in almost quantitative yield (Scheme 13).⁴⁴

Ryu and coworkers also reported a photo-induced Barton reaction, using the DNS photo-microreactor.^{45,46} A key intermediate

for the synthesis of myriceric acid A,⁴⁷ an endothelin receptor antagonist, was obtained using the DNS photo-microreactor. When a photo-microreactor is combined with a compact light source, such as a black light (15 W, peak wavelength: 352 nm) and a UV-LED (1.7 W, peak wavelength: 365 nm), an energy-saving photo-microreaction system is created (Scheme 14).

The photoinduced cyclization of bromoalkynes with triethylamine, originally developed by Cossy *et al.*,^{48,49} provides an attractive radical cyclization process, which does not require group 14 metal hydrides as a hydrogen source. The Ryu group investigated the microflow version of the Cossy reaction using a YMC photo-microreactor

Light source	Glass cover	Residence time (min)	Yield (%)	Wh	Yield/Wh
300 W Hg lamp	soda lime	6	56	30	1.89
15 W black light	Pyrex	12	71	3	23.7
17 W UV-LED	Pyrex	12	70	0.34	206

Scheme 14 Photoinduced Barton reaction using a photo-microreactor combined with an energy-saving, compact light source.

Scheme 15 Photoinduced radical cyclization using a photo-microreactor equipped with a low-pressure mercury lamp.

(KeyChem-Lumino) equipped with a 1.2-W low-pressure mercury lamp (254 nm).⁵⁰ The reaction using the microreactor system gave a cyclization product with a remarkably shortened reaction time of 5 minutes, compared with that of the batch reaction system (Scheme 15). It should be noted that there is a patent for which researchers at GlaxoSmithKline investigated a similar Cossy-type photo radical cyclization.⁵¹ Although a major part of the patent describes a batch reaction, interestingly they noted that a flow photo-reaction is also effective.

4 PHOTO-CARBONYLATION: BATCH TO STOPPED FLOW

Photoinduced atom and group transfer carbonylations provide useful methods to obtain basic carbonyl compounds, such as aliphatic carboxylic acid esters, amides, and seleno esters with incorporation of CO (Scheme 16).^{52–56} For these photoinduced radical carbonylations, a special photo-reaction device, a pressure durable stainless steel autoclave having two quartz windows for irradiation, was employed. Figure 4 shows a

Scheme 16 Photoinduced atom and group transfer radical carbonylation.

Figure 4 Taiatsu Techno's autoclave available for photo-irradiation reaction.

picture of Taiatsu Techno's autoclave available for photo-carbonylation, which was originally designed by Miyashita for the purpose of methane functionalization under photolysis.⁵⁷

One drawback of atom transfer carbonylation was the slow reaction with primary iodoalkanes owing to the relatively low efficiency of iodine atom transfer compared with secondary and tertiary iodoalkanes. However, the Ryu group found that the iodine atom transfer carbonylation of iodoalkanes is markedly accelerated by the addition of transition metal complexes, such as $\text{PdCl}_2(\text{PPh}_3)_2$ and $\text{Mn}_2(\text{CO})_{10}$.^{58,59} This led to the development of a variety of multicomponent reactions with incorporation of CO.^{60,61} Some of the examples are shown in Scheme 17. Thus, cyclizative multiple

carbonylation of alkenyl iodides proceeded to give diketone amides under irradiation conditions in the presence of Pd catalyst.⁵⁸ Acetylenic ketones were obtained by the $h\nu/\text{Pd}$ -induced three-component coupling reaction of alkyl iodides, CO, and terminal alkynes.⁶⁰ Four-component coupling reaction of α -substituted iodoalkanes, alkenes, CO, and alcohols also proceeded well to give functionalized esters (Scheme 18).⁶¹ Pd is required in these cases not only for radical initiation⁶² but also for the formation of acylpalladium complexes in the end, which facilitated the total reaction schemes. Thus, radical and transition metal cooperation function well, which lead to the success of these multicomponent carbonylation reactions.

Photoinduced carbonylation has been recently extended to include efficient C–H carbonylation.²¹ Thus, photo-catalytic radical carbonylation of alkanes with electron-deficient alkenes using tetrakis(tetrabutylammonium) decatungstate as a catalyst gave unsymmetrical ketones in good yields (Scheme 19).⁶³ Here, photo-excited decatungstate abstracts hydrogen from alkanes to form alkyl radicals, which is then added to CO and electron-deficient alkenes consecutively. The reduced form of the photocatalyst ($\text{H}^+\text{W}_{10}\text{O}_{32}^{5-}$) delivers a hydrogen atom to the resulting radicals to give unsymmetrical ketones with the photocatalyst back.

Microflow system for these photo-irradiative carbonylations is yet to be established, but the prototype of a stopped-flow reactor was examined in sample preparation for positron emission tomography (PET), for which biologically active compounds labeled with ^{11}C are widely used as tracers. Långström *et al.* applied the photo-induced atom transfer radical carbonylation to PET labeling

Scheme 17 Multicomponent reactions based on $h\nu/\text{metal}$ hybrid radical carbonylation.

Scheme 18 $h\nu$ /Pd-induced four-component coupling reaction and a possible mechanism.

Scheme 19 Photo-catalytic radical carbonylation of C-H bond of alkanes.

Scheme 20 Photoinduced atom transfer carbonylation using ^{11}C in a stopped flow system.

chemistry using ^{11}C carbon monoxide.⁶⁴ Since ^{11}C has a short half-life ($t_{1/2} = 20.3$ min), fast reactions are required. To realize fast reaction, they developed a special reaction system, using a micro-autoclave, and employed the stopped-flow technique. The system consists of a micro-autoclave (270 μl) equipped with a sapphire window and light source (Scheme 20). The micro-autoclave was filled with ^{11}C in helium, and then the solution of substrates was transferred to the reactor with a 35- to 40-MPa pressure (partial pressure of CO = circa 200–500 Pa). The reaction mixture was irradiated by a light source for several minutes. After the irradiation, the reaction mixture was collected in a product vial through a valve.

Using this system, ^{11}C -labeled carbonyl compounds were synthesized with high radiochemical yields. For example, the reaction of iodocyclohexane with ^{11}C and *N*-phenylpiperazine under irradiation by a 400-W medium-pressure Hg lamp for 400 seconds gave ^{11}C -labeled amide in 65% decay-corrected radiochemical yield (Scheme 20).⁶⁵ ^{11}C -labeled esters and carboxylic acids were also obtained with a similar reaction system.^{66–68} The stopped-flow reaction system is adaptable for fast tracer screening by simply changing either the iodides or the nucleophiles.

5 CONCLUSION

A wide variety of radical reactions, involving group 14 metal hydride-mediated radical reactions, radical carbonylations, radical polymerizations, and photo-induced radical reactions, can be carried out using a microreactor. Shorter reaction time, higher yield and product selectivity, and higher energy efficiency can be achieved using microreaction technology, in which contributions are made by superior thermal efficiency, efficient mixing, precise temperature and residence time control, and efficient photo-irradiation inherent to tiny reaction channels. Some examples verified that gram- to kilogram-scale production can be carried out using a microreactor. Having demonstrated the successful, selective, and efficient performance of a number of important synthetic reactions using microreactors, the new device technology will spread as a useful tool to carry out various thermally and photo-induced radical reactions.

Radical Rearrangements: Ester-Substituted Radicals and Hydrogen Atom Migrations

Kaname Sasaki, Ian Cumpstey and David Crich

*Centre de Recherche de Gif, Institut de Chimie des Substances Naturelles, CNRS, Gif-sur-Yvette
CEDEX, France*

1 INTRODUCTION

In addressing the topic of radical rearrangements, one is immediately confronted by the question of definition as were previous authors faced with a similar task, most notably Beckwith and Ingold in the preparation of their outstanding 1980 opus on the subject.¹ On perusing their chapter, which was written at the dawn of the modern era of the application of radical reactions in organic synthesis and which remains pertinent and informative even today, one is struck by the breadth of the field 30 years ago when it already required 150 printed pages and 786 literature citations for adequate summary. What is equally striking is that virtually all modern classes of radical rearrangement were already known at the time, leading to the conclusion that what has transpired since has been more a revolution in the manner in which radical reactions are viewed, a major and useful part of the synthetic chemistry armory and not simply a series mechanistic curiosities, rather than any great quantum leap forward. What has become apparent since the Beckwith and Ingold chapter is that the very extensive body of thermochemical and kinetic data pertaining to radical reactions, which already stretched to two volumes at the time of Kochi's important compendium in 1973² and which has been enormously extended since, permits, perhaps more than in any other area of preparative

chemistry, the rational, informed planning of sequences of reaction steps for use in preparative chemistry. C–C bond-forming rearrangements, such as the 5-hexenyl–cyclopentylmethyl ring-closure (see **Unusual Cyclizations** and **Radical Cascade Reactions**), and its many cousins, along with C–C bond cleavage reactions such as the cyclopropylmethyl to 3-butenyl rearrangement and aryl radical migrations (neophyl type rearrangements, see **Radicals and Carbohydrates**), are covered extensively elsewhere in this encyclopedia. As such, this article focuses on rearrangements that do not involve reorganization of the basic carbon skeleton of the initial radical but are based on carbon heteroatom bond formations and cleavages and their use in setting up carbon-centered radicals for C–C bond-forming processes. In particular, the focus is on two such rearrangements: those that involve the shifting of esters and related groups and hydrogen atom migration.

2 THE 1,2-SHIFT OF ESTERS

In the early days of the application of free radicals to organic synthesis, a major selling point was the inertness of carbon-centered radicals toward many functional groups such as various carbonyl systems. This changed gradually following the independent discovery of the interaction of carbon radicals with

Scheme 1 β -Acyloxyalkyl radical rearrangement with inversion of carbonyl and carboxyl oxygens.

esters by the Surzur and Tanner groups.^{3–5} Thus, it was demonstrated, serendipitously at first, that certain β -acyloxyalkyl radicals undergo rearrangement to give the more thermodynamically stable radical (Scheme 1).

This novel rearrangement soon attracted the attention of physical organic chemists who determined rate constants and used isotopic labeling methods to demonstrate the inversion of the carbonyl and carboxyl oxygen atoms in the course of the early examples (Scheme 1).⁶ The very simple examples described at that time were found to have rate constants some 100-fold smaller than the prototypical 5-hexenyl radical cyclization, whence the early dictum regarding the inertness of radicals toward esters. Subsequent work, however, following an initial observation from the Kocovsky group,⁷ revealed that some examples of the acyloxy rearrangement are rapid and even exceed the rate of the 5-hexenyl radical cyclization (Scheme 2).^{8,9}

Moreover, the faster examples were found by labeling methods to proceed with a high degree of retention of the original carbonyl and carboxyl oxygens. Much work, experimental and computational, subsequently was conducted on the acyloxy rearrangement which culminated in the hypothesis of two parallel concerted mechanisms, the slower and more typical one involving a five-membered cyclic transition state and a faster, less common one with a three-membered cyclic transition state (Scheme 3).^{6,10}

In agreement with the suggestion of Sprecher,¹¹ subsequent work by Crich, Newcomb, and their coworkers, which focused attention on the influence of polar effects on the rearrangement rate, resulted in the assignment of a mechanism involving the fragmentation of the initial radical to give an alkene radical cation/carboxyl anion pair that undergoes very rapid recombination to the product radical (Scheme 4).^{12,13}

This two-step fragmentation/recombination pathway involving the intermediacy of an alkene radical cation fits the vast majority of the experimental facts and explains, for example, why neither γ -acyloxyalkyl radicals^{3,4} nor β -acyloxy aryl radicals rearrange (Scheme 5).¹⁴ Computational work on the related acyloxyvinyl radicals concludes that such species can undergo rearrangement albeit with a significant barrier and by a fragmentation–recombination pathway.¹⁵

In the early 1990s, the Crich and Giese groups independently reported that phosphate esters,^{16–19} and even nitrate and sulfonate esters,²⁰ undergo a directly analogous rearrangement albeit more rapidly than the typical carboxyl shift. Isotopic and stereochemical labeling experiments revealed these more rapid rearrangements to take place predominantly with retention of the phosphoryl and phosphoryloxy oxygen atoms.^{17–19,21,22} Similar three and five-membered cyclic transition states were drawn for these rearrangements, until the later work of Crich and Newcomb revealed their polar components and even demonstrated directly for the first time the intermediacy of the alkene radical cation.¹³ At the time of writing, this fragmentation–recombination reaction involving an alkene radical cation/anion pair is considered to be general, with the tightness of the ion pair and the rate of recombination determined by the stability of both the alkene radical cation and the anion.²³ Thus, the

Scheme 2 β -Acyloxyalkyl radical rearrangement with retention of carbonyl and carboxyl oxygens.

Scheme 3 Initially proposed three- and five-membered cyclic transition states for the acyloxy migration.

Scheme 5 Acyloxy radicals that do not rearrange.

Scheme 4 Fragmentation/recombination mechanism for the acyloxy rearrangement.

more basic carboxylates lead to a tighter ion pair than the phosphates, resulting in an instantaneous collapse to the product radical and the lack of scrambling of the label typically observed. Beginning even earlier than these studies on the rearrangement reactions, typically conducted in nonpolar solvents, an ongoing series of reactions on the fragmentation of β -acyloxyalkyl, β -(phosphatoxy)alkyl, and

related radicals was conducted in polar protic solvents by physical organic chemists.^{24–28} As was eventually recognized, these fragmentations simply represent the extreme form of the mechanism in which stabilization of the alkene radical cation and its counterion by the medium prevents recombination and leads ultimately to an alternative reaction manifold (Scheme 6). Alkene radical cations generated in this manner may be productively employed in preparative chemistry when intercepted by nucleophiles such as allyl and butenyl amines.^{29–31} Such tandem processes that couple nucleophilic attack with radical cyclization take place with a measure of memory of the absolute stereochemistry of the initial ester, indicating that trapping takes place at least partially at the level of the contact ion pair.^{32–34}

Unlike simple γ -acyloxyalkyl radicals (Scheme 5), alkyl radicals substituted at the

Scheme 6 Unified mechanism for the rearrangement and fragmentation of β -ester-substituted alkyl radicals.

Scheme 8 Lewis acid catalysis of the β -acyloxy alkyl rearrangement.

γ -position with thiocarbonyl esters are capable of rearrangement (Scheme 7). These reactions presumably proceed through a stepwise mechanism with ring-closure to a 1,3-oxathian-2-yl radical with subsequent ring-opening.³⁵

As might be expected from its mechanism, the β -acyloxy alkyl rearrangement can be catalyzed by the inclusion of certain Lewis acids (Scheme 8).³⁶

Lactones may also be caused to undergo both ring contraction (Scheme 9) or expansion by the acyloxy migration depending on the constitution of the initial radical.^{37–40} Cyclic phosphate esters can similarly

be induced to undergo related ring expansions and contractions (Scheme 9).⁴¹

From a preparative standpoint, undoubtedly the most useful examples of the acyloxy shift are those enabling the preparation of 2-deoxy sugars (see **Radicals and Carbohydrates**) (Scheme 10).^{42–48} As Giese pointed out, these rearrangements are thermodynamically favored, as the loss of radical stabilization energy is more than compensated for by the gain of the anomeric effect.^{9,43,49}

Phosphate esters also migrate to the anomeric position under radical conditions. In doing so,

Scheme 9 Radical ring contractions of lactones and cyclic phosphates showing rate constants and labeling patterns.

Scheme 10 Practical synthesis of 2-deoxy sugars by the acyloxy shift.

they generate 2-deoxy glycosyl phosphates which may be employed in glycosylation reactions (Scheme 11).^{16,17,19}

In contrast with the migration to the anomeric center in sugars, it has been demonstrated that acyloxy groups migrate away from the nucleoside 1'-position when a radical is generated at the 2'-center (Scheme 12).^{50–54} Evidently, radical stabilization by two heteroatoms is worth more energetically than the anomeric effect in this example.

The literature on the rearrangements and fragmentations of acyloxy alkyl and related radicals

was reviewed comprehensively in 1997 and again in 2006, when a complete mechanistic picture was presented.^{6,23}

3 HYDROGEN ATOM MIGRATION

The Hofmann–Löffler–Freitag reaction of *N*-haloamines in acidic media giving pyrrolidines is historically perhaps the first example of a hydrogen atom migration.^{55,56} In this reaction,

Scheme 11 Rearrangement to form a 2-deoxy glycosyl phosphate and its subsequent employment in a glycosylation reaction.

Scheme 12 Shift of an acyloxy group away from the nucleoside 1'-position.

an ammonium radical cation abstracts a hydrogen atom from an alkyl chain via a six-membered cyclic transition state to give a δ -aminobutyl radical that undergoes chain transfer by halogen

atom abstraction from a further molecule of *N*-haloamine.⁵⁷ The initial product is therefore a δ -aminobutyl halide that undergoes cyclization on subsequent basification of the reaction mixture

Scheme 13 Mechanism of the Hofmann–Löffler–Freytag reaction.

However, the need to synthesize *N*-haloamines, or their equivalents, and the strongly acidic conditions worked against the extensive use of this reaction in fine synthesis until the development of alternative, more practical entries into electron-deficient, nitrogen-centered radicals.⁶¹

The analogous δ -, or 1,5-hydrogen abstraction reaction by alkoxy radicals took off rapidly as a major synthetic reaction after Barton's seminal synthesis of aldosterone by means of nitrite ester photolysis (Scheme 17).⁶⁹ In this chemistry, hydrogen atom abstraction is followed by selective combination of the alkyl radical with the NO $\cdot$ radical generated in the photolysis step owing to the operation of the Fischer–Ingold persistent radical effect (see **Fundamentals of Controlled/Living Radical Polymerization, Nitroxides in Synthetic Radical Chemistry, and Nitroxide-Mediated Polymerization and its Applications**).⁷⁰ The nitrosoalkane generated in this manner then undergoes tautomerization in the usual manner to give the isolated oxime.⁷¹

Scheme 15 Multiple 1,5-hydrogen abstractions by a sulfonamidyl radical.

Scheme 16 1,5-Hydrogen abstraction by an amidyl radical.

Scheme 17 Key steps in Barton's first synthesis of aldosterone.

Other methods for the generation of alkoxy radicals in preparative systems either directly preceded Barton's contribution or soon followed it, including the use of lead tetraacetate,⁷² the use

of mercuric oxide and iodine,⁷³ and the photolysis of hypohalites^{74,75} and sulfonate esters.⁷⁶ More recently, the combination of iodobenzene diacetate and iodine has been extensively exploited by the

Scheme 18 Houk's computed envelope-like transition state for 1,5-hydrogen atom abstraction by alkoxy radicals.

Suarez group.⁷⁷ The early work on remote hydrogen abstraction by alkoxy radicals has been reviewed a number of times,^{59,60,78–80} and the picture emerges that, as clearly foreseen by Barton, abstraction takes place predominantly through a six-membered cyclic transition state to give a 4-hydroxybutyl radical in the vast majority of cases.⁵⁹ Computational work by Houk revealed the transition state for these hydrogen atom abstractions to resemble more a five-membered ring in an envelope conformation rather than the chair-like six-membered ring envisioned by Barton.⁸¹ In this transition state, the breaking and forming bonds to the migrating hydrogen subtend an angle of $\sim 153^\circ$ (Scheme 18). Recent

kinetic work by the Newcomb group has defined the Arrhenius parameters for the 1,5-hydrogen atom abstraction by simple primary alkoxy radicals in the moderate polarity solvent trifluoromethylbenzene, affording a rate constant of $2.7 \times 10^7 \text{ s}^{-1}$ at 20°C .⁸²

The relatively strict requirements for a quasi-linear transition state at the migrating hydrogen atom strongly disfavor hydrogen atom abstraction through smaller than six-membered cyclic transition states. Indeed, competing alkoxy radical fragmentation is typically the observed reaction pathway when hydrogen atom abstraction is not possible from the δ - or more remote positions. Hydrogen atom abstractions involving seven-membered ring cyclic transition states are well known when the bond energies render them favorable,^{83,84} as in the example of Scheme 19.⁷⁷

Even within the most common series of 1,5-hydrogen atom abstractions, changes in regioselectivity can be affected by subtle changes in molecular conformation that impinge on the ability to achieve the optimal transition state geometry. A case in point is taken from Barton's original work on aldosterone synthesis in which use of the A-ring

Scheme 19 Example of 1,6-hydrogen atom abstraction by an alkoxy radical.

Scheme 20 Barton's second aldosterone synthesis illustrating the dependence of hydrogen-atom abstraction on conformation.

Scheme 21 Abbreviated mechanism for OH-assisted 1,2-hydrogen atom migration.

Scheme 22 Norrish–Yang cyclobutanol synthesis with 1,5-hydrogen atom abstraction by a photoexcited ketone.

enone (Scheme 17) gave only 21% of the oxime resulting from abstraction from the C18 methyl group due in part to competing abstraction from the alternative angular methyl C19.⁶⁹ Conversion of the A-ring enone to the corresponding cross-conjugated dienone, thereby changing the conformation of the steroidal nucleus, more than doubled the yield of the product arising from hydrogen atom abstraction at the desired C18 position (Scheme 20).⁸⁵

The 1,2-hydrogen atom shift in alkoxyalkyl radicals to give ketyl radicals is a known and rapid

process in water or alcohols. Extensive mechanistic work including the determination of deuterium kinetic isotope effects has resulted in the proposition of a number of mechanisms for this reaction of which that of Ingold and coworkers best takes account of all experimental parameters (Scheme 21). In view of the mechanism, this reaction is not a true rearrangement of an alkoxy radical but is included here insofar as it is a serious competing reaction of 1,5-hydrogen atom abstractions of alkoxy radicals

Scheme 23 Remote C–H bond functionalization by an excited state ketone.

when they are carried out in alcoholic or aqueous solutions.^{86–88}

Evidently, the 1,5-hydrogen atom abstraction of alkoxy radicals is closely related to the Norrish type II photoprocess and the Norrish–Yang cyclobutanol synthesis (see **Synthetic Radical Photochemistry**), in which an excited state ketone abstracts hydrogen from the γ -position (Scheme 22).^{89,90}

Photoexcited ketones have been employed to achieve hydrogen atom abstraction from more remote positions when substitution or conformational constraints prevent abstraction from the δ -position (Scheme 23).^{90,91} However, the relatively poor selectivity of such processes for remote functionalization arising from the highly reactive nature of the triplet ketone prompted the development of more selective processes based on weaker hydrogen atom abstracting systems.

The work of Breslow using iodobenzoate esters in the presence of iodobenzene dichloride has set the standard for such remote functionalization processes and enabled the selective functionalization of the

steroid nucleus at a variety of tertiary positions depending on the position of the iodine atom on the benzoate group (Scheme 24).^{91,92}

Although the vast majority of work on hydrogen atom abstraction by heteroatom-based radicals has focused on aminium radical cations and on alkoxy radicals, other oxygen and nitrogen-centered radicals have also been investigated. Thus, while aliphatic carboxyl radicals undergo decarboxylation too rapidly to take part in hydrogen atom abstractions, such processes are known for the much longer lived arylcarboxyl radicals, as illustrated in Scheme 25.⁹³

In recent years, attention has turned from heteroatom-centered radicals to carbon-centered radicals and in particular the use of vinyl and aryl radicals for the abstraction of hydrogen from sp^3 C–H bonds wherein the driving force is evidently provided by the formation of an sp^2 C–H bond at the expense of its weaker sp^3 equivalent. Such processes evidently have very similar requirements for

Scheme 24 Selective remote functionalization of tertiary C–H bonds by iodoarene-derived radicals.

Scheme 25 1,5-Hydrogen atom abstraction by a carboxyl radical.

Scheme 26 1,5-Hydrogen abstraction by a vinyl radical.

a quasi-linear transition state geometry at the migrating hydrogen atom, as their alkoxy and aminium radical counterparts and six-membered cyclic transition states are by far the most common processes.

Although such processes have long been known,¹ one of the earliest examples of their employment in a synthetic context was recorded by Parsons (Scheme 26).⁹⁴

Much subsequent work was conducted by the Curran group, extending this concept of intramolecular hydrogen atom abstraction by vinyl radicals

followed by radical cyclization. The term radical translocation was coined for this process which, because of the need to overcome competing processes, especially vinyl radical reduction by the chain transfer reagent, functions best for hydrogen atom abstraction from the weaker polarized C–H bonds of ethers and acetals.^{95–100}

1,5-Hydrogen abstraction by an aryl radical resulting from an *ortho*-halobenzyl-protecting group on oxygen or nitrogen results in a radical adjacent to the heteroatom. Scheme 27 shows a nitrogen-protecting radical-translocating group, *o*-iodobenzyl. The initial radical is generated using samarium iodide, and a second equivalent of that reagent gives a metallated intermediate which is trapped by electrophiles.¹⁰¹

A variant on the theme employs *o*-haloarylsilyl ethers to generate a siloxyalkyl radical for application in subsequent processes. 1,6- and 1,7-Hydrogen atom abstractions were found to compete significantly with the major 1,5-hydrogen abstraction pathway when the oxygen-protecting group dimethyl(*o*-bromophenyl)silyl was used as a radical precursor, as measured by deuterium incorporation in a tin deuteride reduction (Scheme 28). Nevertheless, this method could be used to introduce a deuterium label regioselectively at C42 into a complex natural product, namely, rapamycin (Scheme 28).¹⁰²

With *O*- and *N*-benzyl (or benzoyl) or *O*-phenylsilyl based protecting translocating groups, 1,5-hydrogen abstraction should result in a radical at the carbon bearing the (protected) heteroatom. Protecting-translocating groups based

Scheme 27 Radical translocation from a protecting group.

Scheme 28 Simple and complex examples of hydrogen atom abstraction from a silylether-based protecting group.

Scheme 29 1,5-Hydrogen atom abstraction in an aryl ether.

on *p*-methoxyphenyl ethers are designed to functionalize more remote unactivated C–H bonds. 1,5-Hydrogen abstraction should result in a radical on the carbon vicinal to the carbon bearing the heteroatom. Curran found that 1,6-hydrogen abstraction was sometimes seen to a significant extent, depending on the substituents on the

radical formed after abstraction. In the example shown in Scheme 29, 1,5-hydrogen atom abstraction is favored by the formation of a tertiary radical.⁹⁷

Along similar lines, carboxylic acids may be protected and activated as amides of *N*-methyl-*o*-iodoaniline. A favorable conformation

Scheme 30 1,5-Hydrogen abstraction from in an anilide.

Scheme 31 1,6-Hydrogen atom abstraction in a benzylideneacetal.

is crucial to successful 1,5-hydrogen abstraction, and this could be potentially problematic in amides with restricted rotation about the amide

bond. Fortunately, the *o*-iodoanilides show a significant preference (>95 : 5) for the required *anti* conformation, and radical translocation to a position α to the carbonyl group is seen (Scheme 30).¹⁰³

A 2-bromobenzylidene group has been used as a protecting-radical-translocating group for 1,2-*cis*diols and was employed in the synthesis of a branched-chain sugar. The rigid *cis*-fused bicycle and *endo* stereochemistry of the benzylidene stereocenter make 1,5-hydrogen abstraction by the radical generated at the *ortho* position of the benzylidene impossible. Therefore, only 1,6-hydrogen abstraction is seen (Scheme 31).¹⁰⁴

A slight redesign of the basic radical translocation concept led to that of self-immolative protecting groups, whereby the *o*-halobenzyl ethers lead to benzyloxyalkyl radicals following 1,5-hydrogen atom abstraction and then, by expulsion of a benzyl radical, to a ketone. In this manner, the oxidation of an alcohol protected in the form of a functionalized benzyl ether to a carbonyl group may be achieved under what are effectively reducing conditions (Scheme 32).¹⁰⁵

As noted above, 1,5-hydrogen atom abstraction typically dominates radical translocation processes,¹⁰⁶ but even the best laid plans go awry. Thus, in a planned inversion of an α -mannopyranoside to its β -isomer by a 1,5-hydrogen atom abstraction from a alkyl radical

Scheme 32 The self-immolative protecting group strategy.

Scheme 33 Unanticipated 1,4-hydrogen atom abstraction encountered by Crich and coworkers.

Scheme 35 1,4-Hydrogen atom abstraction in a severely crowded environment.

Scheme 36 Transannular hydrogen atom abstraction by an alkyl radical.

precursor appended to O_2 , a series of products arising from 1,4-hydrogen abstraction from C2 were seen (Scheme 33).¹⁰⁷ Tackling the same problem, Curran and coworkers relied with moderate success on the weaker nature of the anomeric C–H bond

to achieve the desired process with an aryl radical through a seven-membered cyclic transition state (Scheme 34).¹⁰⁸

Other examples of 1,4-hydrogen atom abstraction by aryl and vinyl-centered radicals are found in the work of the Ingold and Gilbert groups.^{109,110} As in other instances of this kind, the high degree of substitution in the example given (Scheme 35) limits the conformation and results in a relatively facile 1,4-hydrogen atom abstraction.¹¹¹

Intramolecular hydrogen atom abstraction by alkyl radicals is far less common than that by aryl and vinyl radicals, as it obviously does not possess the same thermodynamic driving force. Nevertheless, in favorable circumstances such processes can function, as is clear from Scheme 33. In a further such example, Ourisson, Zard, and their coworkers noted transannular hydrogen atom migration through a six-membered transition state imposed by the rigidity of the bicyclic skeleton (Scheme 36).¹¹²

Intramolecular C–H abstraction reactions may be caused to occur at sp^2 C–H bonds if the abstracting radical is itself an aryl (or presumably vinyl) radical and if competing abstraction from sp^3 C–H bonds is not available. As has been amply demonstrated, such situations occur with *o*-aryloxy aryl radicals and related species including *o*-aryloxyaryl radicals (Scheme 37).^{113,114} In a related work by Scott, a

Scheme 37 1,5-Hydrogen atom migration between two aryl radicals.

Scheme 38 1,4-Hydrogen atom abstraction between aryl radicals in a corannulene synthesis.

1,4-hydrogen atom shift between two sp^2 -hybridized carbons was a crucial step in a synthesis of benzo[*a*]corannulene (Scheme 38).¹¹⁵

1,4-Arenediyls generated by the Bergman cyclization are also susceptible to intramolecular

hydrogen atom abstractions when a C–H bond of suitable bond dissociation energy is correctly disposed. For example, it was demonstrated that a naphthalene-1,4-diyl generated in this manner could be trapped by 1,5-hydrogen atom abstraction,

Scheme 39 1,5-Hydrogen abstraction by a naphthalene-1,3-diyl generated by Bergman rearrangement.

thereby displacing the enediyne-diyl equilibrium (Scheme 39).^{116,117}

4 CONCLUSION

There is a rich and varied chemistry of radical rearrangements beyond the simple formation and cleavage of C–C bonds. This chemistry may be employed to set up C–C bond-forming rearrangements or it may compete with them. Certainly, synthetic chemists need to be aware of such processes, as some are rapid. Alternatively, such rearrangements may be productively employed in systems that do not involve C–C bond-forming reactions at any stage, as in Barton's classical aldosterone synthesis.

Manganese(III) Acetate, CAN, and Fe(III) Salts in Oxidative Radical Chemistry

Jonathan W. Burton

Department of Chemistry, University of Oxford, Chemistry Research Laboratory, Oxford, UK

1 INTRODUCTION

This article covers oxidative radical reactions mediated by manganese(III) acetate (MAN), cerium(IV) ammonium nitrate (CAN), and various iron(III) salts. The formation of C–C bonds will form the focus of this overview. Much of the chemistry of Mn(III), Ce(IV), and Fe(III) involves the formation of electrophilic radicals (or related species) from CH-acidic compounds. These radicals can undergo C–C bond formation with the production of new “adduct” radicals. The adduct radicals can undergo oxidative elimination to form alkenes, or oxidative substitution or ligand transfer to form C–X bonds. Additionally, these adduct radicals can undergo reduction by H-atom transfer from solvent or substrate; overall the substrate has undergone no net redox change in such a reaction. Owing to space limitations, the reduction of adduct radicals will only be mentioned in passing.¹ Additionally, this overview covers only C–X bond-forming reactions^{2,3} in which they are part of a reaction sequence that has involved formation of a C–C bond; aryl–aryl coupling reactions (see **Radical Arylations**)^{4–6} and reactions that are catalytic in metal⁷ are not covered. Applications of the reported methodologies are illustrated in the context of complex molecules synthesis. A number of excellent reviews covering various aspects of the oxidative radical chemistry of manganese, cerium, and iron

are available and should be consulted for comprehensive coverage: Mn(III)^{1,2,8–12}, Ce(IV),^{3,7,13–17} and Fe(III).^{4,6}

2 GENERAL MECHANISMS

In order to be able to rationalize reactivity and plan synthetic routes that involve oxidative radical reactions, it is necessary to have some working knowledge of the mechanisms of such reactions.¹² In its most generic form, exposure of an electron-rich species (most frequently an enol/enolate, an aromatic ring, or a heteroatom) to Mn(III), Ce(IV), or Fe(III) salts results in single-electron oxidation of the organic substrate to generate a free or metal-bound radical or radical cation. The radical/radical cation can then undergo a number of reactions which generally result in the formation of adduct radicals. Oxidative radical reactions differ from more standard radical reactions in the numerous possible pathways available for conversion of these adduct radicals into products. The fate of adduct radicals are discussed below.

MAN (represented in the schematics as Mn(OAc)₃) is an oxo-centered triangle of Mn(III) atoms with bridging acetates,¹⁸ typical of many transition-metal acetates. (In this review, it is assumed that all reactions are conducted with MAN dihydrate rather than anhydrous MAN unless

Scheme 1 Mechanism of γ -lactone formation.

explicitly stated.) The reagent was first used in organic chemistry for the synthesis of γ -lactones from alkenes and acetic acid. The mechanism of the reaction is believed to involve rate-determining deprotonation of a bridging acetate to give the manganese enolate **2** (Scheme 1).^{19–21} Single electron transfer (SET) then occurs to give the electrophilic free radical **3** which adds in a regioselective manner to an alkene to give the more stable secondary adduct radical **4**. Formation of the γ -lactone product **6** from the adduct radical **4** requires a further single-electron oxidation. MAN will not oxidize isolated primary and secondary radicals to the corresponding carbenium ions; however, it will oxidize γ -carboxy radicals to give γ -lactones, and a number of mechanisms have been proposed for this conversion.¹² One possibility is illustrated.

In the reaction between alkenes and CH-acidic β -keto esters, two distinct mechanisms are believed to operate. With α -substituted β -keto esters, formation of the corresponding Mn(III) enolate is believed to be rate-determining followed by rapid

SET to give the corresponding electrophilic radical **10** which undergoes rapid addition to an alkene (Scheme 2).^{22,23} By contrast, with unsubstituted β -keto esters (**7**) and alkenes, formation of the corresponding Mn(III) enolate **8** is fast and the experimental evidence indicates that direct addition of the Mn(III) enolate onto the alkene occurs to give radical **11** and that radical **9** is not formed. Here the tertiary adduct radical **11** would be oxidized by MAN to give a cation **12** which is trapped to give product **13**.

Hence, the more acidic unsubstituted β -keto acids/esters add to alkenes directly from the Mn(III) enolate, whereas with substituted β -keto acids/esters an electrophilic radical is formed which subsequently adds to an alkene. In a similar manner, alkenyl malonates undergo addition/cyclization reactions via the corresponding malonyl free radicals,²³ whereas with alkenyl Meldrum's acid derivatives the Mn(III) enolate undergoes direct addition/cyclization onto an alkene to give the corresponding adduct radical.²⁴

Scheme 2 Mechanisms of addition of β -keto esters to alkenes.

In all these systems, the adduct radical can undergo a number of reactions. As noted previously, Mn(III) readily oxidizes γ -carboxy radicals to the corresponding γ -lactones and will oxidize tertiary radicals to the corresponding carbenium ions which undergo S_N1 and E_1 processes. Mn(III) oxidizes isolated primary and secondary radicals only very slowly, and here hydrogen abstraction from the solvent or substrate is the major pathway. Overall, there is no net change in oxidation level of the substrates (i.e., no net oxidation) and these reactions will be mentioned only briefly. On the basis of the pioneering work of Kochi,²⁵ Heiba and Dessau demonstrated that copper(II) acetate oxidizes secondary radicals to alkenes 350 times faster than MAN.^{26,27} Copper(II) acetate is now widely used in conjunction with MAN to allow efficient oxidation of primary and secondary alkyl radicals generally to give alkenes. A number of these processes are illustrated by the cyclization of 4-pentenyl malonate **14** (Scheme 3).²³ On exposure to MAN, the free radical **18** is formed which cyclizes to an approximate 1:9 mixture of adduct radicals **19**:**20**. In the presence of copper(II) acetate, the corresponding copper(III) intermediates **22** and **21** are formed which undergo β -hydride elimination to give the corresponding alkenes **17** and **16**; in general, oxidative elimination mediated by copper(II) acetate occurs to give the less substituted *E*-olefin (see below). The

γ -lactone **15** is also formed from the copper(III) intermediate **21**, presumably by substitution with one of the carbonyl groups of the malonate followed by hydrolysis. If the reaction is conducted using ethanol as solvent in the absence of a copper(II) salt, then the methylcyclopentane **23** is formed. Here, oxidation of the primary radical **20** by MAN is very slow and hydrogen atom transfer from the solvent occurs to give **23** and the α -hydroxy radical **24** which is oxidized to acetaldehyde **25** by Mn(III); the reduction of vinylic adduct radicals by hydrogen-atom transfer from solvent is synthetically useful.^{1,28,29} Similar mechanisms will be operating with CAN and iron(III) salts.³⁰ With CAN, products of ligand transfer are frequently formed. The use of CAN in acetic acid with $Cu(BF_4)_2$ and malonate **14** gives the γ -lactone **15** in 83% yield, whereas in the presence of acetic anhydride the nitrate **26** is formed in 81% yield by an oxidative ligand transfer mechanism.³¹

The copper(III) intermediates formed in these reactions can also form cyclopropanes (e.g., **27**) presumably by displacement of copper(III) by an enol/enolate (Scheme 4).^{32,33} Adduct radicals formed in the presence of MAN can be directly converted into azides,³⁴ chlorides,^{35,36} carboxylic acids^{37,38} (addition to carbon monoxide), and ketones³⁹ (addition to nitriles).

Baciocchi⁴⁰ and Flowers^{41–44} have studied the mechanism of the addition of β -dicarbonyl

Scheme 3 Mechanisms of product formation from adduct radicals.

Scheme 4 Mechanism of cyclopropane formation.

compounds to alkenes mediated by CAN and by ceric tetrabutylammonium nitrate (CTAN)—an organic soluble version of CAN. Flowers has shown that, unlike related reactions mediated by MAN, CAN and CTAN can directly oxidize enols to form radical cations which can add to alkenes or lose a proton prior to alkene addition (see below).

3 INTERMOLECULAR REACTIONS

3.1 γ -Lactones from Alkenes and Carboxylic Acids

3.1.1 Use of Acetic Acid

The formation of γ -lactones by the reaction of alkenes with acetic acid in the presence of MAN was reported in 1968 by Heiba and Dessau⁴⁵ and Bush and Finkbeiner.⁴⁶ A wide variety of alkenes have been used for this purpose.¹⁹ For example, addition of acetic acid to 1-decene gives the corresponding γ -lactone in 79% yield (1).¹⁹

This procedure has recently been used for the synthesis of a number of carbohydrate-based γ -lactones from 1,2 and 2,3-glycals and acetic acid in the presence of acetic anhydride using ultrasound to

facilitate the reaction. An example is shown in (2).⁴⁷ Here, the regioselectivity of the addition is governed by the interaction of the low-energy singly occupied molecular orbital (SOMO) of the electron-deficient radical **3** interacting with the highest occupied molecular orbital (HOMO) of the glycal—a polarity-matched reaction. The use of MAN and CAN with sugar-based substrates has been widely studied by Linker (see below).^{48,49}

(2)

With other unsymmetrical di- and tri-substituted alkenes, the regioselectivity of γ -lactone formation is a balance of steric factors coupled with the relative stabilities of the adduct radicals. *tert*-Butyl crotonate **29** yields a 3.8 : 1 regioisomeric mixture of γ -lactones **28**, whereas methyl cinnamate **30** gives the corresponding γ -lactones **31** with almost complete regiocontrol, illustrating the enhanced stability of the intermediate benzylic radical (Scheme 5).¹⁹

The functionalization of [60]fullerene (C₆₀) using MAN with acetic acid, propionic acid, or malonic acid to yield the corresponding γ -lactones has been reported.⁵⁰ The oxidation of γ -carboxy radicals by Mn(III) to form γ -lactones also occurs with certain vinyl radicals.⁵¹ The formation of γ -lactones from acetic acid and alkenes mediated by Ce(IV) has been far less investigated than the corresponding Mn(III)-mediated reactions. Heiba and

Scheme 5 Regioselective formation of γ -lactones.

Dessau reported the formation of the corresponding γ -lactone from the reaction between 1-octene or styrene and acetic acid in the presence of CAN or other Ce(IV) salts.^{52,53}

More recently, the direct synthesis of the natural product norbisabolide as a 1 : 1 mixture of diastereomers from limonene and acetic acid mediated by CAN has been achieved (3).⁵⁴ A previous synthesis of norbisabolide involved the reaction of limonene **32** with acetic acid in the presence of MAN and acetic anhydride which gave the diene **33**. The diene **33** was converted to norbisabolide in 43% overall yield on exposure to formic acid.⁵⁵ The formation of **33** from limonene in the presence of MAN is in keeping with the known propensity of acetic anhydride to give reduced yields of γ -lactones in Mn(III)-mediated reactions.^{19,56}

3.1.2 Use of Acetic Acid Derivatives

A wide variety of other carboxylic acids have been used in conjunction with MAN and alkenes to give the corresponding γ -lactones, and the area has been thoroughly reviewed.⁹ Of particular interest is the use of carboxylic acids such as cyanoacetic acid,^{20,53,57,58} malonic acid,^{59–61} and monoalkyl-malonic acids^{20,58,62–66} which have particularly acidic CH protons and therefore will add to alkenes to give γ -lactones using acetic acid as the solvent.

The γ -lactonization methodology using α -substituted malonic acids has been developed and used by Corey in the total synthesis of the biologically active natural products paeoniflorin and paeoniflorigenin.⁶⁷ Exposure of the silyl enol ether **34** to excess cyanoacetic acid in the presence of MAN gave the γ -lactone **35** in 48% yield (4); the major side product was silylated cresol arising from oxidation of the electron-rich substrate **34** under the reaction conditions. In this chemo- and regioselective transformation, the cyanoacetic acid radical adds to the most electron-rich position of the most electron-rich double bond in **34**. The use of CAN for γ -lactone annulation of alkenes with substituted acetic acids has been only sparsely studied.^{54,68} Reasonable yields of the γ -lactone annulation of limonene with cyanoacetic acid, chloroacetic acid, and propionic acid have been reported.⁵⁴

The addition of malonic acids to alkenes and dienes is of interest, as it results in a great increase in molecular complexity in a one-pot reaction (5).^{60,61} The reaction of the diene **36** with malonic acid gives the tricyclic bis-lactone **37**.⁶¹ In this reaction, two C–C bonds, two C–O bonds, three rings, and three stereocentres are formed in a single step from simple linear starting materials.

3.2 Aldehydes and Ketones

Mn(III)-mediated addition of aldehydes to alkenes gives rise to numerous products generally in low yield, and as such are not particularly synthetically useful and will not be discussed further.^{9,10} On exposure to MAN^{26,27} or CAN,⁶⁹ ketones generate α -oxoalkyl radicals. Multiple products are frequently formed in the reaction of ketones with alkenes and yields are frequently modest. The reaction of styrene with acetone in the presence of MAN gives the corresponding acetate **38** in good yield owing to the ready oxidation of the benzylic adduct radical to the corresponding cation which is then trapped by acetate (6).⁷⁰ The reaction of acetone with aromatic compounds mediated by MAN and CAN has been studied.^{71,72}

The allylation of a range of (mainly) cyclic α,β -unsaturated ketones and α -alkoxy and β -alkoxy α,β -unsaturated ketones using anhydrous MAN and allyl bromide in benzene provides an alternative to enolate allylation (7).^{73,74} In the absence of allyl bromide, the α' -acetoxy ketone is formed in excellent yield; this is a general procedure for the α' -acetoxylation of unsaturated ketones.^{75–77}

The addition of ketones to enol acetates gives 1,4-diketones or dimethyl acetals in the presence of either Mn(III)⁷⁸ or Ce(IV).⁷⁹ The use of Ce(IV) gives higher yields of product, although with both metals the yields quoted are with respect to the oxidant in the presence of excess ketone and alkenyl acetate.

Recently, MacMillan has reported a wide variety of catalytic enantioselective oxidative radical reactions which he has termed *SOMO catalysis* (see **Stereoselective Radical Reactions**). The first of a series of publications was concerned with the α -allylation of aldehydes in the presence of CAN (8),⁸⁰ which has since been extended to the catalytic enantioselective allylation of cyclic ketones.⁸¹

The mechanism of this reaction most likely involves initial stereoselective enamine formation between the aldehyde **40** and the amine catalyst

Scheme 6 Mechanism of enantioselective allylation.

39 (Scheme 6).⁸² Oxidation of the electron-rich enamine **41** then occurs to give the radical cation **42** which adds to the allylsilane giving the adduct radical **43**. Oxidation of the adduct radical **43** to the β -silyl cation **44** using a second equivalent of CAN followed by electrofugal loss of silicon and iminium ion hydrolysis delivers the allylated aldehyde **46** and regenerates the amine catalyst **39**.

This is a very powerful synthetic methodology that has been used for the catalytic enantioselective formation of 1,4-dicarbonyl compounds using enol silanes in place of allylsilanes,⁸³ as well as the catalytic enantioselective formation of β -nitroaldehydes, useful precursors to β -aminoaldehydes, using silylnitronates in place of allylsilanes.⁸⁴ The use of styrenes as the radical acceptors in these reactions gives rise to the corresponding γ -nitroaldehydes with control of up to three contiguous stereocenters.⁸⁵ A further asymmetric process involves the use of vinyl trifluoroborate salts for the asymmetric vinylation of aldehydes.⁸⁶

3.3 Addition of β -Dicarbonyl and Related Compounds to Alkenes

3.3.1 Synthesis of Dihydrofurans

The synthesis of dihydrofurans (DHF) from the reaction of β -keto esters and β -diketones with

alkenes mediated by MAN and CAN has been very widely studied since the initial report of Heiba and Dessau.⁸⁷ A wide range of alkenes engage in this reaction.^{88,89} Corey and Mellor demonstrated the use of *endo*-cyclic enol ethers as substrates^{89–91} to form DHFs in the presence of β -keto esters, β -diketones, and esters of acetone dicarboxylic acid. For example, exposure of the enol ether **47** and ethyl acetoacetate to MAN in acetic acid gave the bicyclic enol ether **48** in good yield, which on treatment with acid gave the corresponding furan **49** (9).⁸⁹ Thio ethers and *exo*-cyclic enol ethers can also be used for DHF and sulfur heterocycle synthesis.^{92–95} Other groups have reported the formation of spirocyclic DHFs from 1,1-disubstituted alkenes using MAN⁹⁶ and CAN.^{97,98}

Lee⁹⁹ and others^{100,101} have investigated the addition of β -dicarbonyl compounds to conjugate dienes, including enol ethers, using MAN and CAN. The reaction of **50** with **51** gave the acetal **52**, which was used to prepare the anticancer natural products **53** and **54** (10).⁹⁹ Further examples of the use of **50** as the β -dicarbonyl component in Mn(III)-mediated synthesis of DHFs have been reported.¹⁰²

The addition of β -keto esters and β -diketones to variously substituted alkenes mediated by CAN or CTAN has also been widely studied.^{40,103} Flowers⁴¹ has demonstrated a solvent-dependent synthesis of DHFs (11). Treatment of a range of β -diketones and β -keto esters with styrenes and CAN in methanol or

acetonitrile gave predominantly the DHF (e.g., **56**) or the organic nitrate (e.g., **55**); the nature of the aryl group on the ketonic substrate also affected the product distribution.

In-depth mechanistic analysis led to the following proposed reaction pathway to account for the solvent dependent product distribution (Scheme 7): Direct oxidation of the enol **57** gives the radical cation **58**. In MeOH, the radical cation readily loses a proton to give the radical **59**, which reacts with styrene to give adduct radical **60**. Further single-electron oxidation yields the benzylic cation **61**, which forms the DHF **56** on deprotonation. In the aprotic solvent acetonitrile, the radical cation **58** reacts directly with styrene to give the adduct radical **62**. Further oxidation by Ce(IV) gives the benzylic cation **63**, which suffers from restricted rotation due to intramolecular hydrogen bonding and therefore traps nitrate anion to give product **55**.

Scheme 7 Solvent-dependent DHF/nitrate formation.

Flowers⁴⁴ and Hwu¹⁰⁴ have independently studied the reaction between β -dicarbonyl compounds and allylsilanes to give silyl-containing DHFs or allylated products, depending on the reaction conditions. Flowers has also investigated the use of silyl enol ethers in place of β -dicarbonyl compounds in these reactions. The addition of a 1,3-ketoaldehyde to a silyl enol ether mediated by CAN has been used by Baran in model studies toward the synthesis of maoecrystal V.¹⁰⁵

Vinyl sulfides are excellent substrates for the CAN-mediated formation of DHFs on reaction with β -dicarbonyl compounds with yields generally being higher using CAN rather than MAN.^{106–109} The addition of β -keto esters and β -diketones to indoles to yield DHFs mediated by MAN has also been reported.¹¹⁰

DHFs fused to C₆₀ have been synthesized using both β -keto esters and β -diketones in reasonable yields (based on consumed [60]fullerene).^{111,112} The functionalization of fullerenes with a range of pro-radical species including malonates,^{111,113,114} diallylamines,¹¹⁵ phosphonates,¹¹⁶ β -amino ketones, and esters¹¹⁷ under the influence of MAN has been reported.

Nair and coworkers have widely studied the formation of DHFs by the addition of β -diketones and β -keto esters to a range of alkenes mediated by CAN including a comparative study with MAN.^{101,118–120} In their study, CAN-mediated reactions were generally slightly higher yielding and faster than Mn(III)-mediated reactions. As an example, the addition of acetylacetone to the hindered alkene **64** occurred regioselectively at the less hindered end of the alkene to give the DHF **65** and

the alkene **66** (12).¹²⁰

Various substituted alkenes undergo reaction with CAN or MAN in the presence of β -dicarbonyl compounds with yields generally being higher with substituents on the alkene substrate which are readily able to stabilize the intermediate carbenium ions.^{96,121} The regiochemistry of DHF formation has been investigated using trifluoromethyl acetyl acetone as the β -dicarbonyl component.¹²²

Nishino has developed an efficient route to a wide range of tricyclic and endoperoxide propellanes using tricarbonyl substrates. For example, under anaerobic conditions, exposure of a range of tricarbonyl substrates such as **67** to an electron-rich alkene and MAN gave the propellane **68** (Scheme 8).^{123,124} If rigorous exclusion of oxygen was not achieved, then mixtures of the propellanes **68** and **69** were obtained and conducting

Scheme 8 Formation of propellanes.

A wide variety of β -dicarbonyl equivalents have been used for DHF formation. The natural product 4-hydroxycoumarin has been used as a β -dicarbonyl component in DHF synthesis^{102,129} and for the key step in the synthesis of the natural product fercoprolone.¹³⁰ The nitrogen analog of 4-hydroxycoumarin has been used for the synthesis of araliopsine and related quinoline alkaloids.^{131,132} Other β -dicarbonyl equivalents used in the synthesis of DHFs include β -keto amides¹³³ and β -cyano ketones^{134–136} and 4-hydroxy-2-quinolones.¹³⁷ β -Keto sulfones are also viable substrates for DHF formation under oxidative radical conditions.^{138–141}

The addition of β -dicarbonyl and related compounds to heteroaromatics mediated by MAN or

3.3.3 Addition and Subsequent Cyclization onto an Aryl Ring

Iron(III) catalysts have been used by MacMillan as single-electron oxidants in catalytic

enantioselective addition–cyclization reactions which allow the rapid increase of molecular complexity.¹⁵⁹ A number of aldehydes bearing a diverse range of electron-rich aromatic groups (e.g., thiophenes, indoles, catechols, benzofurans) undergo oxidative coupling–cyclization with a range of styrenes to give cyclohexanes bearing two stereocentres in good yield and with high enantio- and diastereoselectivity. For example, the thiophene-substituted aldehyde **79** undergoes coupling with a range of styrenes in the presence of the organocatalyst **80** and iron(III) hexafluoroantimonate to give the cyclohexanes **81–83** (14); extension of the method to the use of aldehydes bearing allylsilanes was also reported.

In an early example of addition–cyclization using β -dicarbonyl compounds, Citterio reported

the addition of malonyl radicals onto alkenes with subsequent cyclization onto an aromatic ring in the presence of Mn(III), Ce(IV), and Fe(III) salts.¹⁶⁰ This is an efficient process that works with a very wide variety of aromatic and olefinic substrates. As part of this study, diethyl 4-chlorobenzylmalonate **84** and a range of alkenes were treated with MAN in acetic acid at 60°C , CAN in methanol at 20°C , and iron(III) perchlorate in acetonitrile at 20°C (Scheme 9). Both with 1-octene and acrylonitrile, good yields of the corresponding benzannulated products **85** were isolated with Mn(III) and Fe(III) mediators, whereas the use of CAN resulted in the predominant formation of products of oxidative elimination and ligand transfer (not shown). Using styrene as the alkene gave rise to the corresponding γ -lactones **86** in good yield.

The use of alkynes as substrates in similar reactions resulted in the formation of the analogous dihydronaphthalenes, rearranged dihydronaphthalenes, and spirocyclic products.¹⁶¹ In a related study, Citterio reported the reaction of dialkylpyridylmethyl malonates with alkenes and alkynes in the presence of Mn(III), Ce(IV), and Fe(III) salts to give dihydroquinolines or isoquinolines in high yields¹⁶²; the use of 3-picolylmalonates gave regioisomeric mixtures of products with both alkenes and alkynes.

Chuang has widely developed addition–cyclization methodologies using MAN or CAN over a number of years.^{110, 163–165} For example, addition of acetylacetone to 2-amino-1,4-naphthoquinones followed by cyclization onto a pendent aromatic group gives the tetracyclic product **87** along with the tricyclic heterocycle **88** (15)¹⁶⁶; the use of bulkier β -dicarbonyl compounds generally gave the

Scheme 9 Metal-dependent formation of tetrahydronaphthalenes or γ -lactones.

tetracyclic products with higher selectivity. Chuang has reported a similar method for the formation of phenols and furans from 2-benzoyl-1,4-benzo- and naphthoquinones.^{167,168} Addition–cyclization reactions involving heteroaromatics have also been reported.^{169,170}

A powerful synthesis of indanes and δ -aminomalonates by a one-pot Ugi reaction, radical addition–cyclization cascade has recently been reported.¹⁷¹ Thus treatment of a variety of aromatic aldehydes, isocyanides, and carboxylic acids gave the Ugi products (e.g., **89**), which upon treatment with malonates or β -keto esters in the presence of MAN gave indanes or δ -aminomalonates (Scheme 10). The reaction most likely proceeds by formation of the adduct radical **92**, which undergoes neophyl rearrangement to give **93**. Further oxidation of **93** followed by hydrolysis gives **91**. If the malonate still carries an acidic CH proton, further oxidation and cyclization occurs to yield the indane **90**.

Huang has reported an addition–rearrangement–cyclization reaction of a range of β -dicarbonyl compounds with methylene cyclopropanes in the presence of MAN.^{172,173} As an example, exposure of a range of methylene cyclopropanes **95** to an α -cyanoketone and MAN gave the corresponding dihydronaphthalenes **96** (Scheme 11).¹⁷² A likely mechanism for this reaction involves a methylcyclopropyl–homoallyl rearrangement of adduct radical **97** to give **98**, which undergoes cyclization onto the aromatic ring followed by further Mn(III)-mediated oxidation to give the product.

Scheme 10 Cyclization–rearrangement of Ugi products.

Scheme 11 Addition–rearrangement–cyclization to give dihydronaphthalenes.

3.3.4 Addition and Subsequent Cyclization onto an Alkene

The addition of malonates and related β -dicarbonyl compounds carrying pendent unsaturation to olefins followed by subsequent cyclization is a very powerful method for multiple C–C bond formation.^{39,174,175} An example is shown in which spirocyclic products are formed in good yield (Scheme 12).¹⁷⁴ The mechanism of the reaction most likely involves the regioselective addition of the malonyl/acetoacetyl radical **100** to methylene cyclopentane to give the tertiary adduct radical **101**. The adduct radical undergoes rapid 5-*exo*-trig radical cyclization to give the primary radical **102**, which gives the products **104** on oxidative elimination in the presence of copper(II) acetate. This is a powerful synthetic transformation resulting in the formation of two C–C bonds, two

rings, and an alkene in one step from simple substrates.

3.3.5 Other Addition Reactions

Nishino has been very active in the area of Mn(III)-mediated intermolecular radical additions and has reported a number of methods for the synthesis of endoperoxides from alkenes using MAN and a wide range of β -dicarbonyl equivalents including β -diketones,¹⁷⁶ β -keto esters,^{176–178} amides,^{126,176,179,180} sulfoxides,¹⁴¹ sulfones,¹⁴¹ and phosphinates.¹⁴¹ An example of this work involves the formation of endoperoxides from β -keto amides and alkenes with sub-stoichiometric MAN in air at ambient temperature (16).¹⁸⁰ The mechanism for product formation is analogous to that shown in Scheme 8. Diperoxides can also be formed in certain instances.¹⁸¹

Scheme 12 Spirocycle formation by addition and subsequent cyclization.

The intermolecular addition of malonates, nitroalkanes, and related compounds to glycals in the presence of MAN or CAN has been widely studied by Linker for the synthesis of 2-*C*-glycosides. In an early publication,¹⁸² Linker exposed tri-*O*-acetyl-*D*-glucal to dimethyl malonate and MAN or CAN, which delivered the corresponding 2-*C*-glucosides in good overall yield (17); the Ferrier rearrangement product (not shown) was also isolated in 10% yield in the Mn(III)-mediated reactions. A number of other glycals and dialkyl malonates and nitroalkanes^{183,184} have been used in these reactions.^{185,186} Additionally, the complete suppression of anomeric nitrate formation could be achieved by using anhydrous CAN.^{187,188} Disaccharides can also be functionalized using this methodology.¹⁸⁴ The addition of nitroalkenes to non-sugar enol ethers and silyl enol ethers mediated by CAN has also been studied.¹⁸⁹

An interesting synthesis of pyrroles from vinyl azides was recently reported using sub-stoichiometric quantities of MAN (5–40 mol%).¹⁹⁰ One of the many reported examples involves the synthesis of the pyrrole **106** from the triol derivative **105** and ethyl acetoacetate in 74% yield (18). Overall, this is not an oxidation but nevertheless is of mechanistic and synthetic interest.

Chuang has published widely on the synthesis of five-membered aromatic nitrogen heterocycles formed between a range of β -dicarbonyl and related compounds with quinones^{191–197} and vinylogous carbamates^{198,199} in the presence of MAN or Ce(IV) salts. Two of the many examples are shown in Scheme 13, along with a proposed mechanism for pyrrole formation. Thus, pyrroles are readily formed by oxidative radical reaction of β -dicarbonyl compounds with enamines in the presence CTAN or MAN; yields were generally highest when CTAN was used.¹⁹⁸

The addition of malonates to alkenes under the influence of transition-metal salts has been widely studied. In some early studies, Citterio demonstrated that iron(III) perchlorate was an effective mediator of oxidative radical reactions giving γ -lactones (**107**) in good yields (19)²⁰⁰; yields were significantly lower with alkyl-substituted alkenes. The use of butadiene in this reaction resulted in the formation of the corresponding spirocyclic product. The addition of malonates to styrene and related alkenes, under the influence of CAN, gave lower yields of the γ -lactones corresponding to **107**, and mixtures

Scheme 13 Formation of pyrroles from enamines and β -dicarbonyl compounds.

of products were frequently formed.^{120,201,202}

With MAN, dimethyl malonate, and styrene, a low yield of the γ -lactone corresponding to **107** was reported; however, when stilbene was used as the substrate, the corresponding γ -lactone product was formed in 86% yield as a single diastereomer.²⁰³

The addition of dialkyl malonates carrying additional carbonyl functionality to alkenes leads to dihydropyrans in good yield.²⁰⁴ Allenes have also been used as substrates for reaction with dimethyl malonate and ethyl cyanoacetate mediated by MAN.^{205,206}

Enol ethers have been widely used as substrates in oxidative radical chemistry. Corey and Ghosh reported MAN-mediated addition of acetoacetyl radicals to isopropenyl acetate to directly give 1,4-diketones in good yield.⁹¹

Parsons has extended this methodology to the synthesis of a wide range of 1,4-keto aldehydes²⁰⁷ and to an auxiliary controlled diastereoselective synthesis of 1,4-diketones (**20**).²⁰⁸

The use of silyl enol ethers as substrates in CAN-mediated reactions has been widely studied. In early and synthetically interesting examples,^{209,210} Baciocchi reported the synthesis of 1,4-diketones and keto aldehydes by the treatment of silyl enol ethers or ethyl vinyl ether, respectively (Scheme 14). The mechanism of these reactions involves direct oxidation of the electron-rich silyl enol ether with CAN to give a radical cation **108**,

Scheme 14 Dimerization of enol ethers.

Scheme 15 Mechanism of α -thioketone formation.

which either undergoes addition to the second enol ether or gives the corresponding radical **109** followed by subsequent enol ether addition. Oxidation of the adduct radical **110** by CAN gives the corresponding oxocarbenium ion **111**, which readily yields the product. In these reactions, the more electron rich of the two substrates is preferentially oxidized. The addition of silyl enol ethers to ethyl vinyl ether mediated by CAN has been reported by other research groups.²¹¹ The use of silyl dienol ethers and dienes in these reactions has been studied,^{212,213} as well as the reaction between enamines and silyl enol ethers.²¹⁴ It should be noted that silyl enol ethers do not form the corresponding radical cations with MAN, although they can be used as electron-rich acceptors of electrophilic radicals formed in Mn(III)-mediated reactions⁶⁷; more commonly, Mn(III) picolinate is used for such reactions.^{215,216}

The reaction of allyl sulfides and conjugated silyl enol ethers with CAN yields allylated products (Scheme 15).²¹⁷ Here, the electron-rich sulfur atom is readily oxidized by CAN to give the radical cation **112**, which undergoes addition to the silyl enol ether giving **113**. A further single-electron oxidation followed by loss of the silyl group yields the sulfonium salt **114**. Ylide formation with subsequent [2,3]-sigmatropic rearrangement gives product **116**.

The generation of thiocarbenium ions by the oxidation of 2-tributylstannyl-1,3-dithianes and related compounds by Ce(IV) and Fe(III) salts has been studied by Narasaka.^{218,219} These cations react with silyl enol ethers and related electron-rich alkenes to give sulfur-containing products. Of the many examples reported, the reaction of the stannane **117** with a silyl enol ether mediated by ferrocenium hexafluorophosphate is illustrative (Scheme 16).²¹⁹ Thus, single-electron oxidation at sulfur yields the

Scheme 16 Formation and reaction of a thiacarbenium ion.

radical cation **119**, which loses tributyltin radical to give **120**. Reaction of the cation **120** with the silyl enol ether gives the oxocarbenium ion **121**, which on loss of the trimethylsilyl cation gives the product **118**. In a similar manner, *N*-acyl iminium ions are readily formed by oxidation of α -tributylstannyl amides with ferrocenium hexafluorophosphate or CAN and undergo reaction with silyl enol ethers.²²⁰ α -Tributylstannyl esters undergo CTAN-mediated oxidation to give electrophilic radicals, which add to silyl enol ethers and other electron-rich olefins to give 1,4-dicarbonyl compounds.²²¹

3.3.6 Homo and Heterocoupling

The electrophilic radicals that are generally formed at the start of the reaction sequence in many the reactions considered thus far are prone to dimerization, which can occur in synthetically useful yields.^{222–230} Nicolaou has used such a dimerization in the synthesis of the natural product hybocarpone.²³¹ The head-to-head dimerization of 1,3-bis(trimethylsilyloxy)buta-1,3-dienes mediated by CAN has been reported for the synthesis of 1,4-dihydroquinones.²³² Although the homocoupling of enolates mediated by iron(III) salts has been known for a long time,^{228–230} the heterocoupling of enolates has only recently been studied because of the inherent difficulties of realizing an oxidative coupling between two chemically similar entities in high yield without recourse to using one coupling partner in excess. Such a transformation is inherently attractive, as it would give rise to

a 1,4-dicarbonyl compound, which is traditionally more difficult to prepare than the corresponding 1,3 or 1,5 -dicarbonyl compounds. Baran has demonstrated that iron(III) salts are capable of coupling imide enolates with ketone enolates, as well as oxindole enolates with ketone enolates, in synthetically useful yields via an SET mechanism^{233,234}; copper(II) salts were also efficient oxidants for a range of heterocouplings. One of the many examples is shown in (21). Thus, treatment of a mixture of the two substrates **122** and **123** with 2 equiv of lithium di-*iso*-propylamide (LDA) followed by addition of 2 equiv of iron(III) acetylacetonate gave the heterodimer **124** in 52% yield as a 2:1 mixture of diastereomers at the stereocenter adjacent to the ketone.

Scheme 17 Formation of α -acetamido tetralins.

Treatment of electron-rich aromatics with single-electron oxidizing agents such as Ce(IV), Mn(III), and Fe(III) salts results in the formation of radical cations from which a range of products may be formed via C–C and/or C–X bond formation.¹⁶ One of the most impressive examples of such reactions involves the reaction of a range of styrenes with CAN in acetonitrile which gives the α -acetamido tetralins in good yield (Scheme 17).²³⁵ The likely mechanism of this process involves the formation of the radical cation **125**, which reacts with a second molecule of substrate to give the radical cation **126**. Cyclization occurs to give a third radical cation **127**, which loses a proton to give the radical **128**. Further single-electron oxidation occurs to give the cation **129**, which is trapped by acetonitrile to give the product on hydrolysis.

4 INTRAMOLECULAR REACTIONS

4.1 Monocyclization

4.1.1 Cyclizations Involving Carboxylic Acids

The cyclization of radicals derived from β -keto acids and related compounds onto alkenes results

in the formation of bi- and tricyclic γ -lactones in good yield.²³⁶ As an example, treatment of the β -keto acid **130** (X = CH₂) with MAN delivers the tricyclic γ -lactone **131** (X = CH₂) in 63% yield, whereas cyclization from the corresponding malonic half ester **130** (X = O) gave the tricyclic γ -lactone **131** (X = O) in 64% yield (22).

In a related manner, Snider demonstrated the formation of bridged bicyclic γ -lactones on exposure of unsaturated malonic acids to MAN,²³⁷ and Fristad has demonstrated the formation of fused bicyclic γ -lactones by the cyclization of unsaturated malonic acids and derivatives thereof.²³⁸ Paquette has used the MAN-mediated cyclization of malonic acid derivatives in a synthesis of 14-epiupial—the epimer of the natural product upial. Thus, treatment of the malonic acid monomethyl ester **132** with MAN in acetic acid delivered the tricyclic γ -lactone **133** in 68% yield, which was advanced

to 14-epiupial in nine further steps (23).²³⁹

in the formation of mainly oligomeric material.

4.1.2 Cyclizations with Aldehydes and Ketones

The intramolecular oxidative cyclization of ketones mediated by MAN is generally much more efficient than the corresponding intermolecular process. Snider has studied this process widely.^{240–242} As an example, exposure of the methyl ketones **134** to MAN and copper(II) acetate results in the formation of the cyclohexenyl acetates **135** as a mixture of diastereomers (Scheme 18). A plausible mechanism for this reaction is shown. Similar methodology has been developed for the synthesis of a wide range of bridged bicyclic ketones.^{240–243}

Intramolecular ketone cyclizations onto alkynes have been used in the total synthesis of racemic gymnomitrol.²⁴⁴ Thus, treatment of the ketone **136** with excess MAN in a mixed solvent system delivered the tricyclic ketone **137** in 47% yield (62% based on recovered starting material) as a mixture of alkene stereoisomers, which was converted into gymnomitrol in two further steps (24); use of a terminal acetylene substrate resulted

4.1.3 Cyclizations with β -Keto Esters

Cyclization of electrophilic radicals derived from β -keto esters are by far the most extensively explored cyclization reactions and have been used in the synthesis of numerous natural products. As a general guide, oxidative radical cyclizations of substituted β -keto esters are higher yielding than cyclizations of unsubstituted β -keto esters because further oxidation of the product is possible in the latter case. However, unsubstituted β -keto esters can cyclize onto terminal alkenes in the presence of copper(II) acetate to give good yields of cyclopropanes (Scheme 4).^{32,33} A diastereoselective cyclopropanation reaction has been developed²⁴⁵ and used by Brown for the synthesis of furofuran lignan natural products xanthoxylol, epipinoresinol, methylxanthoxylol, and epieudesmin.^{246,247} The key step in these syntheses was the preparation of the cyclopropyl γ -lactone **139** in good yield and 25:1 dr (diastereoisomeric ratio) from the acetoacetate **138** (25).²⁴⁷ Orena²⁴⁸ has reported an analogous chiral auxiliary controlled synthesis of cyclopropanes from methoxycarbonyl acetamides. The synthesis

Scheme 18 Cyclization of methyl ketones.

of substituted cyclopropanes has been reported by Nishino.²⁴⁹

Early work on the cyclization of β -keto esters demonstrated that competition between 6-*endo* and 5-*exo*-trig cyclization is determined both by the alkene substitution pattern and whether the β -keto ester carries a substituent.^{22,36,250–254} As an example, Snider^{36,250} and Peterson²⁵³ developed an efficient synthesis of salicylate esters which relied on over-oxidation of the initially formed cyclohexane to ultimately yield the aromatic product; prevention of product over-oxidation can be achieved by using α -chloro- β -keto esters as substrates.²² The use of MAN and copper(II) acetate resulted in an efficient procedure for the synthesis of 3-alkyl salicylates (26).^{36,250} Here, the general trend for 6-*endo*-trig cyclization with terminal alkenes is illustrated. 4-Alkyl salicylates could be prepared by using MAN in the presence of lithium chloride.³⁶

The 6-*endo* mode of cyclization of β -keto esters has been exploited by Prunet in the synthesis of the ABC ring system of hexacyclinic acid.²⁵⁵ Here, treatment of the complex acetoacetate **140** with MAN and copper(II) acetate gave the tetracyclic

product **141** in 50% yield (27).

6-*Exo*-trig cyclizations of radicals derived from acetoacetates are frequently highly stereoselective, proceeding through chair-like transition states.^{252,256} The synthesis of bridged bicyclic alkenes by 6-*exo*-trig cyclization is feasible (28).²⁵² Here, the acetoacetate **142** gives the alkenes **143** and **144** in good yield. Formation of **143** is a good illustration of the predominant formation of the less substituted *E*-alkene from alkyl copper(III) intermediates.

This methodology has been used by Nicolaou in a total synthesis of the polycyclic skeleton

of vannausol A.²⁵⁷ Formation of the tricyclic acetoacetate **146** occurs in good yield on exposure of **145** to MAN and copper(II) acetate (29).

An early example of a 6-*exo*-trig radical cyclization of a β -keto ester in complex molecule synthesis is shown in (30). The highly functionalized β -keto ester **147** underwent cyclization in the presence of MAN and copper(II) acetate to give the corresponding terminal alkene in quantitative yield²⁵⁸; the tertiary amine may well be protonated under the acidic reaction conditions thereby preventing N-oxidation.

When competition between 6-*exo* and 7-*endo*-trig cyclization arises, mixtures of products favoring the 7-*endo* mode are frequently observed.^{259,260} A 7-*endo*-trig cyclization of an acetoacetate has been used by White in a synthesis of the dihydro derivative of pallescensin D (31).²⁶¹ In this reaction, the 7-*endo*-trig reaction is the exclusive mode of cyclization as the 6-*exo*-trig mode is disfavored by double-bond substitution. The identical transformation in the absence of copper(II) acetate was reported by Ruveda at a similar time.²⁶²

4.1.4 Monocyclizations with Malonates and Related Compounds

The cyclization of malonates to form fused cyclopentane γ -lactones was originally reported by Snider and further studied by others (Scheme 3).²³ Burton has shown that high yields of γ -lactones may be formed by the cyclization of 4-pentenyl malonates in the presence of MAN and copper(II) triflate in acetonitrile and has used this methodology in the synthesis of the cyclopentane-containing natural product 7,11-cyclobotryococca-5,12,26-triene (32).^{263,264} Here, the malonate **148** gave the [3.3.0]-bicyclic γ -lactone **149** in good yield and with >13:1 dr; formation of the major diastereomer was in accord with the Houk–Beckwith model for 5-*exo*-trig radical cyclizations.^{265,266}

The 5-*exo*-trig cyclization of alkenyl malonates in the presence of copper(II) acetate gives rise to alkenes. Reaction of the diene malonate **150** with MAN and copper(II) acetate in acetic acid gave the alkene **151**, demonstrating the rapid trapping of the adduct radical by copper(II) (33).²⁶⁷ Other examples of 5-*exo*-trig cyclization of 4-alkenyl malonates have been reported.^{268,269}

A 5-*exo*-trig cyclization was used as a key step in the synthesis of avenaciolide (34).²⁴⁵ The γ -lactones **152** and **153** were formed as a mixture of diastereomers at the malonate stereocenter, but with complete trans selectivity between the vinyl and octyl side chains. The major diastereomer was advanced to the natural product.

Jahn has championed the use of ferrocenium hexafluorophosphate as a single-electron oxidant for the conversion of lithium enolates into radicals.^{230, 270–275} These radicals undergo cyclization onto appropriately positioned alkenes and the resulting adduct radicals may be trapped with

2,2,6,6-tetramethylpiperidine 1-oxyl (TEMPO) or undergo dimerization or further oxidation giving γ -lactones and alkenes. An example of γ -lactone formation is shown in Scheme 19.²⁷³ Thus, treatment of the malonate **154** with LDA, or BuLi, gives the lithium enolate **156** which is oxidised by the ferrocenium hexafluorophosphate to give the malonyl radical **157**; the radical cation **158**, derived by oxidation of di-*iso*-propylamine with the iron(III) salt, is the likely oxidant with other metal enolates. The malonyl radical **157** undergoes cyclization to give a doubly benzylic adduct radical, which undergoes further oxidation to give product **155**.^{270,273,274} For certain substrates, the adduct radicals formed in these reactions can be trapped by TEMPO to form C–O bonds.

An advantage of this method compared with the use of MAN and CAN is that it is not a requirement to have a particularly CH-acidic compound such as a malonate or a β -keto ester; esters themselves are good substrates. Cyclization of an ester substrate has been demonstrated in the total synthesis of 15-F_{2t}-isoprostane (35).^{275,276} Thus, cyclization of the lithium enolate derived from the diene **159** occurred in good yield to give the cyclopentane **160** as a mixture of diastereomers, which were readily processed into 15-F_{2t}-isoprostane. Pyrrolidines have

Scheme 19 Oxidative radical cyclization using ferrocenium hexafluorophosphate.

also been synthesized by this method.²⁷⁷

Tandem conjugate addition of lithium amides,²⁷¹ lithium enolates,²⁷² or lithium alkoxides²⁷⁸ to α,β -unsaturated esters or equivalents followed by oxidative radical cyclization–TEMPO trapping has been used to synthesize pyrrolidines, cyclopentanes, and tetrahydrofurans. In related work, treatment of unsaturated nitro compounds with sodium hydride followed by oxidation with CAN yields cyclized products.^{279,280}

Cossy has investigated the reactions of β -keto carboxamides and their corresponding enamines in

the presence of MAN.^{281–283} Some of the many examples are shown in Scheme 20. Using anhydrous MAN in ethanol, **161** gave the methyl-substituted pyrrolidinones **163** in 56% yield as a 7 : 1 mixture of diastereomers. Here, the diastereomeric mixture of adduct radicals undergo H-atom transfer from ethanol to give products. Alternatively, in the presence of copper(II) acetate, oxidative elimination occurs to give the alkene **162**. Interestingly, the use of the enamine substrate **164** resulted in complete reversal of stereoselectivity for the formation of the methyl-substituted pyrrolidinones **163**.

There have been far fewer studies concerning the cyclization of unsaturated malonates using Ce(IV) and Fe(III) salts. Efficient 6-*endo*-trig cyclization of malonates has been reported with an appropriately sterically and electronically biased system. Thus, exposure of the malonate **165** to iron(III) perchlorate in acetonitrile gave the bicyclic γ -lactone **166** in good yield (36).²⁰⁰ 5-*Endo*-trig cyclization reactions of acetoacetamides^{284–286} and α -(methylthio)acetamides have also been reported mediated by both MAN and CAN.^{287–289}

4-*exo*-trig Cyclizations of acetoacetamides under the influence of MAN or CAN are also possible with appropriately sterically and electronically

Scheme 20 Formation of spirocyclic amides.

biased systems, offering a novel route to β -lactams (37).^{290,291}

4.1.5 Monocyclizations of β -Diketones and Enolate Coupling

β -Di- and tri-ketones are some of the most reactive substrates for Mn(III)-mediated cyclizations with reactions generally being conducted at room temperature.²⁵² Mono-cyclization of such substrates has been used as a key step in the synthesis of a number of natural products. Snider developed a formal synthesis of upial by 6-*exo*-trig cyclization of the β -diketone **167**, which yielded the [3.3.1]-bicyclic diketone **168** as a mixture of stereoisomers in 85% yield (38).²⁹² A highly unusual 5-*endo*-trig cyclization has been used to synthesize model compounds related to the natural product fredericamycin A.^{293,294}

The intramolecular oxidative coupling of enolates has not been widely used in natural product synthesis, although intramolecular oxidative aryl-aryl couplings mediated by numerous transition metals have been extensively studied.⁴ The intramolecular coupling of two ketone enolates mediated by

iron(III) chloride²⁹⁵ was used in the synthesis of hirsutene (39).

A more complex example was recently reported by Baran in the synthesis of stephacidin A.²⁹⁶ Here, exposure of the diketopiperazine **169** to 2 equiv of LDA and 2 equiv of iron(III) acetylacetonate gave the product **170** in 61% yield as a single diastereomer (40). This is an impressive transformation given the array of potentially oxidizable groups within the substrate.

4.1.6 Direct Cyclization onto an Aromatic Ring

Intramolecular α -arylation reactions under oxidative radical conditions are generally higher yielding processes than the corresponding intermolecular reactions. The enantioselective α -arylation of aldehydes mediated by iron(III)²⁹⁷ or CAN^{298,299} has recently been developed. An example is shown in (41).²⁹⁷ Thus, treatment of the aldehyde **171** with the imidazolidinone catalyst **172** in the presence of iron(III) phenanthroline hexafluorophosphate and

various additives gave the α -aryl aldehyde **173** in 80% yield and 98% ee. The mechanism of the reaction is closely related to that depicted in Scheme 6.³⁰⁰ The cyclization of α -keto radicals onto aromatic rings has been used in a formal synthesis of parvifoline.³⁰¹

Most oxidative radical cyclizations onto aromatic rings involve the now ubiquitous β -dicarbonyl and related compounds. A great deal of work in this area has been conducted by Citterio using Fe(III),^{30,302,303} Mn(III),^{302–304} and Ce(IV) salts.^{302,305,306} The cyclization of malonates to form tetrahydronaphthalenes works equally well with any of the three metal oxidants (42).³⁰² Cyclization of the homologous malonate to give the corresponding seven-membered compound has been unsuccessful because of competing 1,5-hydrogen atom transfer and benzylic radical formation.³⁰⁴ The use of β -diketones with MAN or CAN allows the synthesis of the seven-membered rings fused to aromatic

rings without interference from 1,5-hydrogen atom transfer.^{307,308}

One of the first examples of the arylation of a β -keto ester mediated by cerium(IV) salts used cerium(IV) sulfate, although the product was formed in low yield.³⁰⁹ Cyclization of β -keto esters onto electron-rich aromatics in the presence of CAN gives the corresponding naphthalenes in modest yields³⁰⁵; MAN generally gives the products in reduced yields. One of the many examples is the formation of the naphthol **175** in 62% yield on treatment of the β -keto ester **174** with CAN followed by heating with silica gel (Scheme 21). The mechanism of this reaction involves formation of the adduct radical **177**, which undergoes oxidative rearomatization followed by further oxidative ligand transfer to give **179** (X = OAc, OMe, NO₃, or OH). Heating **179** with silica gel gives the naphthol **175**.

Cyclization of related compounds using MAN allows the synthesis of dihydronaphthalenes,³¹⁰ quinolines and dihydroquinolinones,^{311–313} indolines and indolinones,^{313,314} naphthoquinones,³¹⁵ and the spirocyclic core of fredericamycin.³¹⁶ The

Scheme 21 Naphthol formation mediated by CAN.

naphthoic acid component of neocarzinostatin chromophore has been synthesized by the cyclization of the reactive β -ketotrifluoroethyl esters in the presence of MAN.³¹⁷

An oxidative Pictet–Spengler reaction related to the work of Naraska has been developed by Mariano (43).³¹⁸ Here, treatment of trimethylsilylmethyl amides (e.g., **180**) with CAN yields the corresponding tetrahydroisoquinolines (e.g., **181**). The reactions proceed by the generation of an *N*-acyl iminium ion by single-electron oxidation at nitrogen followed by electrofugal loss of silicon followed by further single-electron oxidation. Cyclization onto the *N*-acyl iminium ion followed by rearomatization delivers product **181**.

In some early work, Kende developed an efficient intramolecular oxidative coupling of phenoxides with enolates and nitronates.^{319–322} A range of cyclic CH-acidic compounds, on treatment with base and potassium ferricyanide, delivered the corresponding spirocyclic compounds in good yields; the cyclization of acyclic enolates was generally unsuccessful, and cyclizations that formed five-membered rings were generally more efficient than those to form six-membered rings.^{319,321,322} An example is shown in Scheme 22, along with a plausible mechanism for product formation.³²¹ Thus, the substrate **182** undergoes double deprotonation to give the dianion **184**. Oxidation of the enolate by iron(III) gives the β -dicarbonyl radical **185**, which undergoes 5-*exo*-trig radical cyclization to give the radical anion **186**. Further single-electron oxidation gives the product **183**.

In a similar manner, the corresponding nitro compounds undergo spirocyclization and further cyclization–rearrangement, ultimately yielding tropolone derivatives.³²⁰ This methodology has been recently exploited by Kim in the total synthesis of the cytotoxic natural product pareitropone.³²³ Here, treatment of the nitro compound **187** with excess base and potassium ferricyanide delivered the spirocyclic dienone **188**, with concomitant removal of the butenone group and oxidation to the isoquinoline (44); exposure of the isoquinoline to a Lewis acid

Scheme 22 Oxidative coupling of phenoxides and enolates.

gave the natural product pareitropone by a cyclopropanation–electrocyclization sequence.

Cyclization reactions onto heteroaromatic rings have also been studied and used in the synthesis of a number of natural products. Ketorolac, a powerful non-narcotic analgesic, was synthesized by cyclization of the malonate **189** with *in situ* generated MAN (45).¹⁵⁶ The product **145** was converted into ketorolac in two further steps.

A second synthesis of ketorolac involving a diastereoselective oxidative radical cyclization was

recently disclosed by Baran, which utilized an iron(III)-based oxidant to mediate C–C bond formation (46).^{324,325}

Kerr has more fully investigated the cyclization of malonyl radicals onto pyrroles under the influence of MAN and demonstrated that it is a general process for pyrroles, indoles, and indolines; indolines undergo *in situ* oxidation to indoles prior to cyclization. Malonates, acetoacetates, and β -diketones all cyclized to give the corresponding indoles in similar yields (47).^{326,327} The β -diketone **192** was advanced to the natural product meriscarpine.³²⁷ In related work, a range of indolequinones were readily prepared by cyclization of β -dicarbonyl compounds onto indoles.³²⁸

4.2 Tandem and Higher Cyclizations

Oxidative radical cyclizations are an exceedingly powerful method for the synthesis of polycyclic products by the formation of multiple C–C bonds in a single reaction with stereocontrol (see **Radical Cascade Reactions**). In particular, cyclizations to give six-membered rings are frequently highly stereoselective, as they proceed via well-organized chair transition states.²² A few early examples serve to illustrate the power of these oxidative radical cyclizations. Thus, the β -keto ester **195** forms the tricyclic product **196** in 83% yield as a single diastereomer (48).²⁵⁰ If this reaction is conducted in the presence of copper(II) acetate, the product **196** is formed in 66% yield, indicating that cyclization onto an aromatic ring is faster than oxidation of the adduct radical by copper(II); with other substrates these processes can be competitive.²² Bertrand has investigated similar reactions with allyl malonates which lead to a diverse array of products.³²⁹

Formation of tricyclic products is shown in (49).²⁵¹ Here, cyclization of the methyl-substituted β -keto ester **199** delivers the tricyclic product **200** in 50% yield as a single diastereomer and demonstrates that cyclization occurs from the β -keto ester radical with the ester group in a pseudo-axial orientation anti to the ketone carbonyl group; this is a general feature of these cyclization reactions.^{237,251,256} With the unsubstituted β -keto ester **197**, the stereochemistry of the ester-bearing stereocenter is set by equilibration of the product **198**. The tricyclic ketone **200** has been used to synthesize the ethyl ester of *O*-methylpodocarpic acid.³³⁰ The synthesis of closely related β -keto esters bearing different aromatic substituents has been used to prepare triptotoquinones B and C³³¹; cyclizations involving the addition of an adduct radical onto a furan have also been demonstrated.³³²

A related reaction that involves cyclization from silyl enol ethers has been reported by Snider.³³³ Exposure of the silyl enol ether **201** to CAN gave the tricyclic product **202** in 73% yield (Scheme 23). A plausible mechanism for the transformation is shown; in general, copper(II) triflate gave improved yields of the cyclized products. In a related work, unsaturated ketene thioacetals give fused bicyclic γ -lactones in moderate yields on treatment with excess CAN in acetonitrile–water mixtures.³³⁴ Related to this and to the allylation of β -dicarbonyl compounds with allylsilanes reported by Flowers (Section 3.3.1), the intramolecular allylation of allyldimethylsilyl enol ethers mediated by CAN yields α -allyl ketones, offering a nontraditional route to these compounds.³³⁵

Absolute stereocontrol in the cyclization of β -keto esters and related compounds was originally studied by Snider. Initially, β -keto sulfoxides were found to be good cyclization substrates, which gave excellent asymmetric induction but modest yields of cyclized products.³³⁶ Later, the use of various chiral auxiliaries was investigated. Snider demonstrated that 8-phenyl menthol efficiently controlled the sense of asymmetric induction in the cyclization of β -keto esters; however, the sense

Scheme 23 Cyclization involving silyl enol ethers.

of induction was markedly dependent on substrate structure.³³⁰ Yang investigated related cyclizations and demonstrated that lanthanide triflates can markedly increase the rate and stereoselectivity of Mn(III)-mediated cyclizations of β -keto esters.^{337–339} Moreover, the combination of lanthanide triflates, 8-phenylmenthol, and related chiral auxiliaries gives absolute stereocontrol in the cyclization of β -keto esters. This has resulted in enantioselective syntheses of triptolide, triptonide, triptophenolide,³³⁹ triptocallol,³⁴⁰ and wilforonide.³⁴¹ The key step in the asymmetric synthesis of triptophenolide is shown in (50).³³⁹ Exposure of the β -keto ester **203** to MAN and ytterbium triflate in trifluoroethanol at -5 °C gave the tricyclic product **204** in 77% and 38:1 dr. The cyclization is believed to occur from the reactive conformation **205**. It is proposed that the ytterbium triflate promotes enolization of the substrate and, by chelation, renders the β -keto ester radical more electrophilic and holds it in a syn conformation (**205**) during cyclization. The use of ytterbium triflate allows the reaction to be conducted at a low temperature, thereby enhancing the stereocontrol.

Tandem cyclizations of β -diketones onto alkenes have been used in a total synthesis of the anti-tumor antibiotics okicenone and aloesaponol III. Cyclization of **206** with MAN delivers the naphthol **207** in 60% yield (51).^{342,343} Here, the radical derived from **206** undergoes exclusive 6-*exo*-trig cyclization because of the presence of the chlorine atom. Treatment of the naphthol **207**

with boron tribromide delivered okicenone. A related cyclization has been used for the synthesis of a benzoxanthene for use in molecular recognition.^{344–346}

Cyclizations of β -dicarbonyl radicals involving two alkenes have also been widely studied. Cyclizations onto *E*-trisubstituted alkenes proceed exclusively by the 6-*endo*-trig mode as expected and have been widely studied by Zoretic^{347,348} and Snider^{237,256}; cyclizations involving *Z*-trisubstituted alkenes have been far less studied and give mixtures of products.³⁴⁹ In an early example that demonstrates the power of the methodology, treatment of the acetate **208** with MAN in acetic acid gave a mixture of the corresponding bicyclic compounds **209** and **210** with excellent stereocontrol (52).²³⁷ The formation of seven- and eight-membered rings in related reactions has been reported.^{259,260}

Zoretic has demonstrated the cyclization of a closely related substrate **211** in the presence of MAN and copper(II) acetate, which delivered the *exo*-cyclic alkene **212** as a single stereoisomer in 58% yield (52); the alkene **212** was used to synthesize norlabdane oxide.³⁵⁰ The same reaction of **211** to give **212** was recently used for the synthesis of the originally proposed structure of wentilactone B.³⁵¹ A MAN-mediated 6-*endo*, 6-*exo*-trig cyclization of β -keto esters reported by Zoretic³⁴⁷ has been used in studies toward the synthesis of heteroscyphic acid A.³⁵² Similar 6-*endo*, 5-*exo*-trig reaction sequences of β -keto esters give rise to *cis*-fused hydrindans.^{330,348} Triple^{353–356} and quadruple^{357,358} cyclizations of β -keto ester substrates are also feasible. A key step in the synthesis of spongiatriol is shown in (53).³⁵⁹ In this impressive transformation, three C–C single bonds and six stereocenters are formed.

A quadruple cyclization has been used to prepare a D-homosteroid (54).³⁶⁰ Thus, the tetraene **213** delivered the tetracyclic double-bond regioisomers **214**, **215**, and **216** in 61% yield; treatment of the mixture with trifluoroacetic acid gave predominantly the alkene **215**. Complete control of the relative stereochemistry of the products occurs as a result of the chair-like nature of the cyclization transition state.

The termination of cyclization reactions does not always have to involve oxidative elimination to give alkenes. In an approach to sesquiterpene–phenol natural products, Wallace has demonstrated that treatment of the β -keto ester **217** with anhydrous MAN in acetic acid gave the γ -lactone **218** in 58% yield (55).³⁶¹ This is an impressive transformation, as it forges three adjacent quaternary stereocenters in a single step.

Chen has investigated 5-*exo*-6-*endo*-trig tandem cyclizations in highly complex systems as a potential route to the oriodin family of natural products which include palau'amine.^{362,363} In one example, the β -keto ester **219** gave the corresponding tetracyclic product **220** in 60% yield as a single stereoisomer on treatment with MAN in acetic acid (56).

Cyclization reactions to give bridged bicyclic structures have also been investigated^{23,254,256,364–366} and have been used in the preparation of a gibberelic acid intermediate.²⁵⁴ A beautiful example of a quadruple cyclization to form both fused and bridged ring structures is demonstrated in the synthesis of isosteviol and beyer-15-ene- 3β ,19-diol (**57**). Here the tetraene **221** undergoes consecutive 6-*endo*, 6-*endo*, 6-*endo*, 5-*exo*-trig cyclizations to deliver a single stereoisomer of **222** in 35% yield.³⁶⁷

Danishefsky has used the tandem cyclization of a β -diketone as a key step in the synthesis of the

neurotrophic illicinones.^{368,369} Thus, treatment of the silyl enol ether **223** with MAN and copper(II) acetate delivers the tetracyclic product **224** in 70–80% yield (58). It is proposed that under the reaction conditions the silyl enol ether **223** is hydrolyzed to give a β -diketone from which radical formation occurs. A 5-*exo*, 5-*exo*-trig cyclization occurs which ultimately gives the alkene **224**.

In related work, Simpkins has recently reported the synthesis of a 1:1 mixture of ialibinones A and B from the diketone **225** by a 5-*exo*, 5-*exo*-trig radical cascade (59).³⁷⁰

Porco has reported a most impressive synthesis of polycyclic triketones from dearomatized phloroglucinol.³⁷¹ One of many examples is shown in (60). Thus, treatment of the cyclohexadienone **226** gives the pentacyclic product **227** in 76% yield. In this reaction, four C–C bonds and four rings are formed

in a single step, illustrating the power of oxidative radical cyclizations in organic synthesis.

4.3 Ring-Opening and Other Reactions

From the above discussion, it is clear that MAN can mediate enormously powerful transformations in organic synthesis resulting in the formation of multiple C–C bonds frequently with control over multiple stereocenters. In almost all of the above transformations, in order to commence the reaction sequence it is necessary to form a manganese enolate or equivalent subsequent to oxidative SET. In contrast, CAN is able to mediate oxidative SET from substrates that cannot enolize. As with MAN, CAN is capable of single-electron oxidation of electron-rich aromatic rings. Indeed, one of the most widespread uses of CAN in organic synthesis is for the removal of electron-rich benzyl protecting groups such as the 4-methoxybenzyl and 2,4-dimethoxybenzyl groups, which Floreancig has developed into a mild procedure for the formation of oxocarbenium ions.^{372–376} The ability of CAN to form radical cations from electron-rich aromatic rings has been exploited by Nair in an elegant synthesis of disubstituted tetrahydrofurans.^{377,378} Thus, treatment of the ether **228** with CAN in methanol under air gave the ketone **229** in 56% yield,

Scheme 24 Formation of THFs from radical cation cyclization.

Scheme 25 Synthesis of a tetrahydropyran.

whereas conducting the reaction under anaerobic conditions delivered a 2:1 mixture of the methyl ether **230** and the nitrate **231** in 80% yield (Scheme 24); only trans-disubstituted tetrahydrofuran (THFs) were formed. A plausible mechanism for the reaction is shown. Thus, oxidation of the electron aromatic ring in **228** occurs to give a radical cation **232**, which yields a second radical cation **233** on cyclization. Quenching of the cation

by methanol followed by further oxidation delivers the products. This reaction was applicable to a wide variety of bis-aromatic substrates, and cyclization was also achieved with a dimethallyl moiety as the radical acceptor; however, allyl, methallyl, or propargyl ethers failed to undergo cyclization. The synthesis of *N*-tosyl pyrrolidines, pyrrolidinones, and cyclopentanes by this method has been reported.^{379,380}

Scheme 26 Ring expansion of a cyclopropanol silyl ether.

This work has been extended to the synthesis of diastereomerically pure tetrahydropyrans by the cyclization of epoxypropyl cinnamyl ethers. Thus, the epoxide **235**, on treatment with sub-stoichiometric quantities of CAN, gave the tetrahydropyran (THP) **236** as a single diastereomer, along with minor amounts of hydroxy nitrates formed by direct ring-opening of the epoxide **235** (Scheme 25).³⁸¹ The postulated mechanism is based on the work of Iranpoor, who has studied the ring-opening of epoxides with heteroatom-based nucleophiles catalyzed by CAN and garnered evidence for a radical-based pathway.^{382–385} It was proposed that oxidation of the epoxide **235** by CAN delivers the radical cation **237**, which undergoes stereospecific ring-opening to give the radical cation **238** followed by reduction with Ce(III) to give **239**. Ritter reaction of **239** gives the product **236**. The use of *tert*-butanol as the solvent gave the corresponding hydroxy *tert*-butyl ethers. This method

was extended to the stereoselective synthesis of piperidines.³⁸⁶

Other ring-opening reactions mediated by Mn(III), Fe(III), and Ce(IV) have been studied. Booker-Milburn has developed an efficient cyclopropane opening–C–C bond-forming reaction for the synthesis of fused bicyclic systems.^{387–393} As an example, treatment of the cyclopropyl silyl ether **240** with iron(III) chloride delivered the ring-expanded ketone **241** in 64% yield (Scheme 26).³⁸⁷ The reaction is believed to proceed by oxidative formation of the β -keto radical **242**, which undergoes 5-*exo*-trig cyclization to give the adduct radical **243**. Ligand transfer mediated by iron(III) chloride gives the product.^{387,392} The methodology is applicable to the formation of other bicyclic carbocycles. Moreover, if iron(III) nitrate is used in place of iron(III) chloride, the adduct radicals undergo H-atom abstraction instead of ligand transfer with the formation of a C–H bond.^{391,392}

Narasaka has used Mn(III) picolinate for analogous ring-expansion reactions of cyclopropanols,^{394,395} which has resulted in the synthesis of 10-isothiocyanoguaia-6-ene.^{396,397} Related ring-openings of aminocyclopropanes in the presence of CAN have been reported.^{398,399} In a similar manner, oxidative ring-expansion reactions of cyclobutanols mediated by MAN have been reported by Snider⁴⁰⁰ and used in the total synthesis of silphiperforin-6-ene and methyl cantabradienate.⁴⁰¹

Ring-opening of cyclopropyl acetals in the presence of CAN leads to β -carboxy radicals which undergo C–C bond formation. An example is shown in Scheme 27.⁴⁰² Here, the cyclopropyl acetal **244**

Scheme 27 Ring-opening C–C bond formation in the synthesis of disubstituted ketones.

yields the nucleophilic β -carboxy radical **246** on treatment with CAN. Addition of **246** to cyclopentenone occurs selectively to give the electrophilic adduct radical **247**, which reacts with nucleophilic allyltrimethylsilane to give the β -silyl radical **248**. Oxidative loss of the silyl group from **248** gives the product **245**. The ring-opening of cyclopropyl sulfides with concomitant C–X or C–C bond formation has been widely studied by Takemoto and Iwata.^{403–407}

5 CONCLUSIONS

The use of Mn(III), Ce(IV), and Fe(III) salts to mediate oxidative radical reactions has great utility in organic synthesis. In particular, MAN has been shown to mediate some exceptionally powerful stereocontrolled transformations of β -dicarbonyl compounds. It is certainly the case that similar chemistry mediated by CAN and particularly iron(III) salts is underdeveloped and much work remains to be done. Perhaps more exciting, though, are the highly enantioselective transformations that have recently been discovered by merging oxidative radical chemistry and organocatalysis which will likely provide a rich seam of research for years to come. Moreover, new and exciting transformations are being reported that involve oxidative radical reactions, and the development of oxidative radical reactions that are catalytic in metal are beginning to be explored.⁷ In summary, oxidative radical chemistry has delivered a range of exceptionally powerful synthetic methods and we confidently predict that in the future many new important developments will be forthcoming.

1 INTRODUCTION

Oxidation reactions that are initiated by the formation of superoxide radicals ($O_2^{\bullet-}$) during mitochondrial respiration, inflammation, or phagocytosis^{1–6} are present in living cells.^{6–9} Generation of $O_2^{\bullet-}$ may be followed by its enzymatic dismutation into H_2O_2 ,¹⁰ which does not exhibit significant reactivity toward DNA¹¹ with the exception of a rather minor and highly specific reaction giving rise to N^1 -oxide adenine.¹² Reduction of H_2O_2 by transition metals such as ferrous ions (Fe^{2+}) is known to lead through the Fenton reaction¹³ to the generation of the highly reactive hydroxyl radical ($\bullet OH$), the most deleterious reactive oxygen species (ROS), which reacts with proximal biomolecules at the site where it is generated. It is well documented that $\bullet OH$ undergoes addition to the double bonds of nucleobases^{11,14} and hydrogen atom (H) abstraction reaction from the methyl group of thymine^{11,14} and 5-methylcytosine¹⁵ the 2-amino group of guanine¹⁶ together with abstraction reactions from the 2-deoxyribose moiety¹⁷ at rates that are diffusion controlled.¹⁴ The reactions

of H_2O_2 with copper ions that are also present in cells¹³ have been shown to give rise at least partly to other ROS and oxidizing processes. Evidence has been provided for the generation of singlet oxygen (1O_2) by the $Cu(I)-H_2O_2$ system, whereas $Cu(II)-H_2O_2$ has been shown to degrade guanine by one-electron oxidation.^{18–20} Another possible reaction of $O_2^{\bullet-}$ is its radical combination with nitric oxide ($NO\bullet$), which is produced by nitric oxide synthase during inflammation reactions.^{6,13,21} The resulting peroxynitrite (^-OONO) may promote rather multiple types of reactions including nitration together with $\bullet OH$ -mediated and one-electron oxidation. The latter reaction is accounted for by the reaction of ^-OONO with bicarbonate leading to unstable nitrosoperoxycarbonate,^{6,22} which rapidly undergoes decomposition into nitrating NO_2 and the one-electron oxidizing carbonate ion ($CO_3^{\bullet-}$).²³ Among common exogenous oxidants, one may underline ionizing radiation as being able to generate $\bullet OH$ and promote the ionization of DNA components through indirect and direct effects, respectively.¹⁴ One-electron oxidation of the bases could be achieved in a milder way

either by using ultraviolet A (UVA) excited type I photosensitizers^{24,25} or on exposure to high-intensity UVC laser pulses as the result of biphotonic ionization.^{26,27} Another major environmental oxidant is the UVA component of solar radiation, which on excitation of the endogenous photosensitizers, is able to generate predominantly $^1\text{O}_2$ and to a lesser extent $\text{O}_2^{\cdot-}$ through type II and type I photosensitization mechanisms, respectively.²⁸

A large body of information is available on the oxidation reactions of DNA as discussed in several recent review articles.^{29–40} This article focuses on the survey and critical review of oxidative pathways mediated by $^1\text{O}_2$, $^{\cdot}\text{OH}$ and one-electron oxidants to nucleosides, oligonucleotides, and isolated DNA in aqueous solutions. Emphasis is placed on oxidation reactions that have been shown in most cases to occur in cells and that have been validated in model studies using aqueous systems through the detection of known final degradation products. In this respect, mostly single-radical-hit modifications, which include single-base lesions, tandem intrastrand cross-links, and clustered damage, are reported and discussed. One may point out that for lack of space, other types of base modifications induced by ozone^{41,42} or HOCl ^{43,44} or indirectly by breakdown products of lipid peroxides^{25,45–48} are not discussed in the article. The same applies to oxidized bases and nucleosides released in biological fluids such as urine^{49–51} or formed in ribonucleic acids.^{52,53}

Information is also provided on several DNA oxidation products that have been shown to be generated in cells mostly using the accurate high performance liquid chromatography–tandem mass spectrometry (HPLC–MS/MS) method.^{51,54–57} Numerous data obtained by using gas chromatography (GC), HPLC–MS, ^{32}P -labeling, and immunodetection assays are not reported because of the major drawbacks in these methods as discussed in a recent review article.⁵⁸ This is not the case of enzyme-based assays involving DNA repair enzymes such as the formamidopyrimidine DNA *N*-glycosylase and endonuclease III. The enzymes are used for recognizing base damage and strand breaks thus formed are measured with the alkaline comet assay,^{59,60} the unwinding method,⁶¹ or the alkaline elution technique.⁶² However, the latter indirect and more global assays do not provide accurate structural information because of the broad

substrate specificity of the repair enzymes used, and therefore, these assays will not be reported in the present survey.⁶³ As a final remark, the analysis of oxidation products has been confined to nuclear DNA because the quality or the amount of mitochondrial DNA is not sufficient at this time for accurately measuring oxidized bases and nucleosides.

2 SINGLE-BASE DAMAGE

2.1 Singlet Oxygen Oxidation of Guanine

Singlet oxygen ($^1\text{O}_2$) in the $^1\Delta_g$ state ($E = 22.4 \text{ kcal mol}^{-1}$) which is generated in cells by type II photosensitizers or enzymic reactions involving myeloperoxidase^{33,64} is a dienophile⁶⁵ that exclusively reacts at neutral physiological pH with guanine among the DNA components.^{66,67} This contrasts with molecular oxygen (O_2) in its triplet state, which as a biradical reacts efficiently with most carbon-centered radicals. The reaction of $^1\text{O}_2$ with 2'-deoxyguanosine (**1**; Scheme 1) and related guanine model compounds in aqueous solutions has been shown to yield, as the main primary oxidation products, the 4*R** and 4*S** diastereomers of spiroiminodihydantoin nucleosides **8**,^{68,69} initially misassigned as the position isomers of 4-hydroxy-8-oxo-7,8-dihydro-2'-deoxyguanosine **5**,⁷⁰ with a relatively minor contribution of 8-oxo-7,8-dihydro-2'-deoxyguanosine (**4**).^{70–72} More recently, evidence was provided on the basis of HPLC–MS/MS measurements for the generation of **5** as a minor degradation product of **1**.⁷³ The formation of stable oxidation products **4**, **5**, and **8** may be rationalized in terms of a Diels–Alder [4+2] cycloaddition of $^1\text{O}_2$ across the imidazole ring of the base moiety of **1** (Scheme 1) leading to a diastereomeric pair of 4,8-endoperoxides **2**. Evidence for the formation of the latter instable intermediate (**2**) was gained from the nuclear magnetic resonance (NMR) characterization of the related endoperoxides generated by $^1\text{O}_2$ oxidation of 2', 3', 5'-*O*-*tert*-butyldimethylsilyl-8-methylguanosine in CD_2Cl_2 at low temperature.⁷⁴ In a subsequent step, **2** is expected to rearrange giving rise to 8-hydroperoxy-2'-deoxyguanosine (**3**)^{74,75} as indirectly supported by low temperature NMR analysis of a type II photosensitized

Scheme 1 $^1\text{O}_2$ oxidation reactions of the guanine moiety (1) of nucleosides and DNA.

2',3',5-*O*-*tert*-butyldimethylsilyl derivative of 8- ^{13}C -guanosine in an organic solution.⁷⁶ Reduction of **3** is likely to lead to 8-hydroxy-2'-deoxyguanosine, which is in dynamic equilibrium with the predominant 6,8-diketo tautomer (**4**),⁷⁷ while competitive dehydration gives rise to the unstable quinonoid 2-amino-7,9-dihydropurine-6,8-dione (**6**),⁷⁸ which after the addition of water across the 5,7-double bond leads to **8** through the intermediacy of the unstable 5-hydroxy-7,8-dihydro-2'-deoxyguanosine (**7**).⁷⁹ It is worth mentioning that in isolated DNA, $^1\text{O}_2$ oxidation of **1** leads to the overwhelming formation of **4** at the exclusion of detectable amounts of **8** because of steric effects that favor linearization of **2** over dehydration.^{67,80}

Evidence was provided that, in cellular DNA, the reaction of $^1\text{O}_2$ with **1** occurs with the same selectivity and specificity as in aqueous solutions of DNA, generating **4** as the only detectable HPLC–MS/MS oxidized nucleoside.^{64,81} This was achieved using a clean source of $^1\text{O}_2$ that was released in the vicinity of nuclear DNA on incubation of cells at 37 °C with a suitably protected thermolabile naphthalene endoperoxide.⁸² It was confirmed using [^{18}O]-labeled $^1\text{O}_2$ that **4** arises from $^1\text{O}_2$ oxidation of **1** and not indirectly as the result of an oxidative stress induced by the incubation of cells with naphthalene endoperoxide. Several reports have shown that UVA irradiation of cells^{64,83} and human skin⁸⁴ leads through photodynamic effects⁷² to an increase in the level of **4** in nuclear DNA. This, at least in human monocytes, is explained on the basis of a detailed mechanistic study,⁸⁵ in terms of major

contribution of $^1\text{O}_2$ of up to 80% as the result of a type II photosensitized reaction promoted by endogenous photosensitizers. The remaining 20% of **4** was accounted for by $\cdot\text{OH}$ -mediated oxidation by a different mechanism as will be discussed later. Another clarification of a controversial issue concerning the putative DNA nicking activity of $^1\text{O}_2$ was provided by the almost total lack of generation of DNA strand breaks and/or alkali-labile sites as inferred from the results of a comet assay analysis of cells exposed to a specific chemical source of $^1\text{O}_2$: naphthalene endoperoxide.⁸⁶ It has been also shown that UVA irradiation of cells leading to the predominant formation of $^1\text{O}_2$ is not able to generate any detectable amounts of DNA double-strand breaks.^{87,88}

2.2 Hydroxyl Radical Reactions

A convenient way to generate $\cdot\text{OH}$ under well-controlled conditions in model studies is to use the indirect effects of ionizing radiation. Thus, γ -radiolysis of aerated aqueous solutions gives rise to $\cdot\text{OH}$ and $\text{O}_2^{\cdot-}$ in 45 and 55% yields, respectively.^{14,89}

2.2.1 Thymine

The main oxidation products of the base moiety of thymidine (**9**; Scheme 2) mediated by

$\cdot\text{OH}$ in aerated aqueous solutions have been isolated and characterized on the basis of extensive ^1H and ^{13}C NMR, mass spectrometry, and X-ray diffraction measurements.^{90–96} Thus, nine hydroperoxides, which represent about 50% of the total oxidized nucleosides were assigned, consisting of the *cis* and *trans* diastereomers of 6-hydroperoxy-5-hydroxy-5,6-dihydrothymidine (**14**) and 5-hydroperoxy-6-hydroxy-5,6-dihydrothymidine (**16**)⁹⁷ together with 5-(hydroxyperoxy-methyl)-2'-deoxyuridine (**18**). The structures of hydroperoxides **14**, **16**, and **18** were confirmed by chemical synthesis using well-established methods.⁹⁸ In addition, the X-ray crystal structure of *cis*-5-hydroperoxy-6-hydroxy-5,6-dihydrothymine was solved and its electronic properties were inferred from *ab initio* theoretical investigations.⁹⁹ A mixture of the nine hydroperoxides **14**, **16**, and **18** was fully resolved by reverse-phase high-performance liquid chromatography (RP-HPLC) using a colorimetric based post-column reaction for hydroperoxides.¹⁰⁰ HPLC–MS/MS also appears to be a powerful method for detecting hydroperoxides as illustrated by the measurement of hydroperoxide **18** after enzymatic hydrolysis of calf thymus DNA that was exposed to γ rays in aerated aqueous solutions (Ravanat and Cadet, unpublished). The rest of the thymidine degradation products consist of stable nucleosides that are ranged in the following order of decreasing quantitative importance: *N*-(2-deoxy- β -D-*erythro*-pentofuranosyl) formylamine (**21**) > the four *cis* and *trans* diastereomers of 5,6-dihydroxy-5,6-dihydrothymidine (**19**) > the (*5R**)- and (*5S**)-forms of 1-(2-deoxy- β -D-*erythro*-pentofuranosyl)-5-hydroxy-5-methylhydantoin (**22**) > the (*5R**)- and (*5S**)-diastereomers of 1-(2-deoxy- β -D-*erythro*-pentofuranosyl)-5-hydroxy-5-methylbarbituric acid (**20**) > 5-(hydroxymethyl)-2'-deoxyuridine (**23**) > 5-formyl-2'-deoxyuridine (**24**). On the basis of indirect characterization of the primary pyrimidine radicals **10** and **11**, and the structural assignment of final oxidation products **14**, **16**, **18–24** (*vide supra*), a comprehensive mechanism for the $\cdot\text{OH}$ -mediated oxidation of thymidine (**9**) has been proposed (Scheme 2). The predominant reaction of $\cdot\text{OH}$ with the base of free nucleoside **9** is the addition at carbon C-5^{14,101,102} generating the reducing C-6 centered radical **10** in 60% yield. The oxidizing C-5 radical **11** that arises from the addition of $\cdot\text{OH}$ at C-6 is formed with a lower efficiency (35%). A third and minor process

(5%), at least for the free nucleoside, consists of hydrogen atom abstraction from the methyl group, generating the aromatic radical **12**. In a subsequent step, transients **10–12** are converted into the corresponding peroxy intermediates **13**, **15**, and **17** through a fast diffusion-controlled reaction with O_2 .¹⁰³ About half of the peroxy radicals **13**, **15**, and **17** are transformed after $\text{O}_2^{\cdot-}$ reduction and subsequent protonation into hydroperoxides **14**, **16**, and **18**.¹⁰⁴ The half-life of thymidine hydroperoxides varied from 1 to 35 hours at 37 °C for 5(6)-hydroxy-6(5)-hydroperoxides (**14**, **16**), with a much greater half-life for 5-(hydroperoxymethyl)-2'-deoxyuridine (**18**)⁹⁸. The decomposition of **14**, **16**, and **18** was quite specific in aqueous solution in the absence of transition metals. The *trans* and *cis* diastereomers of thymidine 6-hydroperoxides (**14**) initially undergo dehydration to give 5-hydroxy-5-methylbarbituric acid nucleoside (**20**), which in turn can transform by hydrolysis into an open-chain ureid: *N*³-tartronoylurea nucleoside (not shown). In a recent theoretical investigation, the thermal decomposition of 6-hydroperoxide (**14**) was found to be significantly facilitated by water molecules with dehydration being the most favorable initial reaction.¹⁰⁵ In contrast to thymidine 6-hydroperoxides (**14**), the main decomposition pathway of thymidine 5-hydroperoxides (**16**) involved initial cleavage of the 5,6-pyrimidine bond followed by either loss of formic acid and cyclization to give 5-hydroxy-5-methylhydantoin (**22**) or loss of a pyruvyl group to give formylamine (**21**). In the presence of trace or added metal ions, the decomposition of **14**, **16**, and **18** shifted to metal-catalyzed reduction of the hydroperoxides to the corresponding alcohols (**19** and **23**). In addition, aromatic hydroperoxide **18** has been shown to be converted partly into aldehyde **24** on dehydration. It may be added that in the case of free nucleoside **9**, thymine hydroperoxyl radicals **13**, **15**, and **17** may undergo competitive dismutation reactions giving rise to the corresponding highly reactive oxyl radicals.¹⁴ The latter radicals are expected to undergo hydrogen atom abstraction leading to the formation of **19** and/or β scission giving rise to **21** and **22**. However, these reactions are not possible in DNA where peroxy radicals are reduced to hydroperoxides and/or react with vicinal purine and pyrimidine bases leading in

Scheme 2 $\cdot\text{OH}$ -mediated oxidation reactions of the thymine (9).

the latter case to tandem base modifications (see Section 3). Two single-base lesions including **19** and **22** were shown to be formed in double-stranded DNA (dsDNA) on exposure to $\cdot\text{OH}$ in aerated aqueous solutions.¹⁰⁶ In addition, evidence was provided for the $\cdot\text{OH}$ -mediated formation of **24** in DNA.¹⁰⁶ Subsequently thymidine glycols (**19**), 5-(hydroxymethyl-2'-deoxyuridine (**23**), and 5-formyl-2'-deoxyuridine (**24**) have been found to be generated by ionizing irradiation in either aerated aqueous solutions of DNA^{54,107} or cellular DNA in a dose-dependent manner. This was achieved in both cases by using the accurate HPLC-MS/MS method.^{108–110} The similarity between the degradation patterns of **9** in isolated DNA and nuclear

DNA is strongly indicative of the relevance of using aqueous solutions as model studies for investigating the effects of $\cdot\text{OH}$ on cellular DNA. It may be noted that the radiation yields of **19**, **23**, and **24** in cellular DNA are about three orders of magnitude lower than those measured in isolated DNA. Interestingly, a similar shielding effect that is exerted by the cellular components is observed on the levels of radiation-induced damage to the 2-deoxyribose moiety of DNA.¹⁷ As discussed further in Section 2.3, it may be pointed out that the degradative action of ionizing radiation on cellular DNA is mostly explained in terms of the indirect effect mediated by $\cdot\text{OH}$.

2.2.2 Cytosine and 5-Methylcytosine

The intermediates and stable products involved in the $\cdot\text{OH}$ -induced decomposition of cytosine derivatives **25a** are presented in Scheme 3; compounds denoted with the letter **a** refer to cytosine derivatives, whereas those with **b** refer to 5-methylcytosine derivatives. The initial reaction of $\cdot\text{OH}$ with the base moiety of cytosine derivatives proceeds by addition to the 5,6-double bond giving mainly 5-hydroxy-5,6-dihydrocytos-6-yl (**26a**) and partly 6-hydroxy-5,6-dihydrocytos-5-yl (**27a**) in a ratio

of approximately 9:1.^{111,112} Similar to thymine and uracil, the $\cdot\text{OH}$ -adducts of cytosine likely react rapidly with O_2 in aerated aqueous solutions to form the corresponding peroxy radicals: 5(6)-hydroxy- 6(5)-hydroperoxyl- 5, 6-dihydrocytosine radicals (e.g., **28a** and **30a**). The intermediate peroxy radicals of cytosine derivatives may undergo a number of reactions depending on the chemical environment: reduction, bimolecular decay, or reaction with either the flanking bases or sugar moieties of DNA. The formation of the radical cation of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine has been observed on pulse radiolysis of an aqueous

Scheme 3 $\cdot\text{OH}$ -mediated oxidation reactions of cytosine (**25a**) and 5-methylcytosine (**25b**).

oxygenated solution of cytosine, suggesting the formation and reduction of peroxy radicals.¹¹¹ Although the hydroperoxides of cytosine (**29a** and **31a**) have been tentatively characterized, they are not stable under aqueous and neutral conditions.¹¹³ The oxidation products of cytosine **25a** can be divided into three groups: 5,6-glycols and 5-hydroxypyrimidines (**32–35**; 40% of total); C4–C5 cleavage products (imidazolidine (**37**), biuret (**38**), and carbamate (**39**) products; 23%), and fragmentation products (5-hydroxyhydantoin (**40**) and formylamine (**21**; 15%).

The major decomposition pathway of alkoxy, peroxy, or hydroperoxide intermediates of cytosine derivatives involves the formation of cytosine 5,6-glycols (**32a**), which subsequently undergo either dehydration to 5-hydroxycytosine (**33**) or hydrolytic deamination to uracil 5,6-glycols (**34a**). The half-life of cytosine 5,6-glycols is approximately 1 hour at 37 °C and 5 hours at 22 °C in aqueous solution at pH 7 and they predominantly undergo dehydration from pH 2 to 8 (>90%) with an increase in deamination at higher pH (>8).¹¹⁴ In contrast, the half-life of **32a** in DNA was estimated to be 28 hours at 37 °C and pH 7, and the ratio of dehydration to deamination was 1.5:1 in favor of dehydration in oxidized calf-thymus DNA as estimated by acid hydrolysis and HPLC with electrochemical detection (HPLC–EC).¹¹⁴ Similar results were obtained for double-stranded poly(dG–dC) treated with KMnO₄, which more specifically induces the formation of the *cis* diastereomers of **32a**.¹¹⁵ Although these studies have utilized indirect methods to measure cytosine 5,6-glycols **32a** in DNA, they strongly suggest that the double-stranded structure of DNA substantially increases the half-life of **32a** and shifts the decomposition pathway toward deamination in comparison to the monomer. This is reminiscent of changes in the half-life of 6-hydroxy-5,6-dihydrocytosine in poly(dG–dC) (18 hours) compared to that of the monomer (25 min) in aqueous solution at 37 °C and pH 7.¹¹⁶ The yield of **33**, **34a**, and **35** as determined by enzymatic digestion and HPLC–EC, was 19, 16, and 24 lesions per million cytosine per Gy, respectively, in calf-thymus DNA exposed to ionizing radiation in aerated aqueous solutions.¹¹⁷ Again, these results point to an increase in the extent of deamination in dsDNA compared to the monomer. Interestingly, the yield of 5-hydroxyuracil (**35**) was comparable to that of

5-hydroxycytosine (**33**) on exposure of DNA to ionizing radiation, whereas **35** was not detected on exposure of DNA to KMnO₄. This suggests that **35** is not formed by consecutive deamination and dehydration (**32** → **35**). The average steady-state levels of endogenous DNA damage in human lymphocytes was 2.9 ± 1.4 for 5-hydroxycytosine (**33**) and 4.5 ± 1.8 for 8-oxo-7,8-dihydroguanine (**4**) per 10⁶ guanines ($n = 10^5$) as determined by HPLC–EC.¹¹⁸ The levels of 5-hydroxycytosine (**33**) in cellular DNA obtained by HPLC–EC compare closely to those obtained by HPLC–MS/MS. The results suggest that 5-hydroxycytosine (**33**) is generated in cellular DNA at comparable levels to 8-oxo-7,8-dihydroguanine (**4**), whereas the amount of 5-hydroxyuracil (**35**) is at least 10-fold lower.^{119,120}

The formation of products **37a–39a** constitutes a novel pathway of 'OH-mediated decomposition for cytosine derivatives (Scheme 3). The imidazolidine products consist of four diastereomers with two chiral centers (C4 and C5 of the imidazolidine ring), which remarkably, undergo ring-chain tautomerism involving both N1–C5 and N3–C4 bonds of the ring, leading to epimerization of all four diastereomers.¹²¹ The rate of epimerization was much greater for *cis* diastereomers ($8.5 \times 10^{-4} \text{ s}^{-1}$ (half-life = 14 min) compared to *trans* diastereomers ($5.8 \times 10^{-6} \text{ s}^{-1}$; half-life = 33 hours) at 37 °C and pH 7. The mechanism of formation of **37a** likely involves intramolecular rearrangement of 5-hydroxy-6-hydroperoxides, **29a** into C6–C4 endoperoxides followed by O–O and C4–C5 bond cleavage to give intermediate **36a**. This was supported by the formation of imidazolidine products on the reaction of 5-bromo-6-hydroxy-5,6-dihydro-2'-deoxycytidine with H₂O₂, which proceeds by the initial formation of intermediate 5-hydroxy-6-hydroperoxides (**29a**). Additional evidence for the formation of an intermediate endoperoxide was provided by ¹⁸O₂-labeling experiments showing the incorporation of two ¹⁸O atoms into the structure of product **37a**, that is, one label on each at the sides of O–O bond cleavage.¹²² In addition to **37a**, two other nucleosides with a related structure were identified in the mixture of products: biuret (**38**) and aminocarbonyl[2-amino]-2-oxomethylcarbamic acid (**39a**). The open-chain intermediate resulting from C4–C5 cleavage of the endoperoxide may be proposed as a common precursor for all of

the products (**36** $\rightarrow$ **37–39**). The formation of biuret products (**38**), which exist in four different forms (α - and β -furanose, and α - and β -pyranose), due to protonation at N1 and ring-opening of 2-deoxyribose moiety, may be explained by either loss of glyoxal (CHO–CHO) from the intermediate (**36a**) or from the imidazolidine product (**37a**). The formation of **39a** may be explained by the subsequent α -hydroxyketone rearrangement of the precursor (**36a**), followed by dehydration and hydrolysis at C2. The *trans* diastereomers of **37a** have been detected on γ -irradiation of aerated aqueous solutions of dGpdC, dCpdG, and d(TpApCpG), as well as by the reaction of Fenton reagents with dCpC.^{123,124} Using LC–MS/MS, the endogenous steady-state level of a dinucleotide containing imidazolidine (**37a**) in DNA extracted from white extracted from white blood cells was estimated to be 7.7 lesions /10⁶ DNA bases, higher than the amount of either formylamine (**21**) or thymine 5,6-glycol (**19**).¹²⁵

The chemistry of $\cdot$ OH-induced decomposition of 5-methylcytosine derivatives is similar in many respects to that of cytosine derivatives. The main products observed after γ -irradiation of an aerated aqueous solution of the nucleoside (**25b**; Scheme 3; R² = CH₃) included the corresponding derivatives of 5,6-dihydroxy-5,6-dihydro-5-methylcytosine (**32b**), 1-carbamoyl-4,5-dihydroxy-5-methyl-2-oxo-imidazolidine (**37b**), aminocarbonyl[2-amino]-carbamic acid (**39b**) and formylamine (**21**).^{126,127} The four *cis* and *trans* diastereomers of 5-methylcytosine 5,6-glycols (**32b**) undergo deamination to thymidine 5,6-glycols (**19**) with a half-life of 17 and 22 hours for *cis*-(5*S*, 6*S*) and *cis*-(5*R*, 6*R*) diastereomers, respectively, at 37 °C and pH 7; in contrast, the *trans* diastereomers undergo deamination more efficiently than the *cis* diastereomers. Thus, 5-methylcytosine 5,6-glycols **32b** are more stable than cytosine glycols **32a** by about 20-fold for the corresponding nucleosides. Interestingly, there was no marked difference in the half-lives for the deamination of 5-methylcytosine 5,6-glycols (**32b**) as a monomer compared to that in duplex DNA at 37 °C (half-life between 27 and 37 hours).¹²⁸

2.2.3 Guanine

The two main $\cdot$ OH-mediated degradation products of 2'-deoxyguanosine (**1**) in aerated aqueous solution have been identified as 2,2-diamino-4-[(2-deoxy- β -D-*erythro*-pentofuranosyl) amino] -5 (2*H*) -oxazolone (**47**) and its unstable precursor, 2-amino-5-[(2-deoxy- β -D-*erythro*-pentofuranosyl) amino]-4*H*-imidazol-4-one (**46**).^{129,130} In addition, traces of 8-oxo-7,8-dihydro-2'-deoxyguanosine (**4**), which is a ubiquitous DNA oxidation product since it is generated as well by ¹O₂, one-electron oxidants, ONOO[−]^{11,37,131}, and addition of vicinal intrastrand thymine 5(6)-hydroxy-6(5)-hydroperoxyl radicals^{132,133} were found to be formed in a manner independent of the γ radiation dose. The formation of **46** and **47** (Scheme 4) may be rationalized in terms of initial $\cdot$ OH-mediated H[•] abstraction from the 2-amino group of the guanine base¹⁶ and not from $\cdot$ OH addition at the C4 position as proposed earlier.^{134–136} The resulting aminyl radical **41** undergoes tautomerization to guanyl radical **42**, which has been shown to react in nucleosides and oligonucleotides with O₂^{•−}¹³⁷ and not with O₂, as in the case of other highly oxidizing radicals derived from the one-electron oxidation of tyrosine and tryptophan.³⁵ The 5-hydroperoxide **43** thus formed is likely to undergo a complex set of reactions and rearrangements (Scheme 4) including the initial addition of a water molecule addition across the 7,8-double bond giving rise to **44**, followed by opening of the pyrimidine ring at C5–C6 bond and decarboxylation.^{37,129,138} The intermediate **45** is likely to lose a formamide residue as shown by GC–MS analysis leading to the formation of poorly stable **46**. The latter compound has a half-life of 10 hours in neutral aqueous solutions at 20 °C when inserted into oligonucleotides with a quantitative hydrolytic conversion into **47**.¹³⁹ The formation of **4** is explained by $\cdot$ OH addition at C8 leading to the minor reducing 8-hydroxy-7,8-dihydro-7-yl radical **48** (Scheme 5), which represents only 17% of the total guanine radicals.^{135,136} One-electron oxidation of **48** gives rise to **4**, whereas competitive reduction, which is a minor process in aerated aqueous solution for isolated nucleoside, is accompanied by the opening of the imidazole ring at C8–N9 bond with subsequent formation of the 2'-deoxyribonucleoside derivative of 2,6-diamino-4-hydroxy-5-formamidopyrimidine

Scheme 4 Oxidation reactions of guanine (**1**) through $\cdot\text{OH}$ -mediated $\cdot\text{H}$ abstraction from the 2-amino group.

Scheme 5 Oxidation reactions of guanine (**1**) through $\cdot\text{OH}$ addition at C8.

(**49**).^{29,31,37} The low amount of $\cdot\text{OH}$ -mediated formation of **4** is accounted for by its efficient one-electron oxidation as soon as it is produced by the oxidizing guanine radical **42**. However, the presence of a reducing agent such as ascorbic acid in a mixture of H_2O_2 and Fe^{2+} ions, the so-called Udenfriend reagent, leads to the predominant formation of **4**¹⁴⁰ at the expense of **47**. This may be explained by the reduction of precursor radical **42**, which prevents the oxidation and consumption of **4**.

Exposure of DNA in aqueous aerated solution to the indirect effects of ionizing radiation has been shown to give rise to significant amounts of **4** with smaller amounts of **49**, both degradation products arising partly from initial $\cdot\text{OH}$ addition at C8 of **1**.⁵⁴ This contrasts with the low yield of formation of **4** on $\cdot\text{OH}$ oxidation of free **1**, which may be explained by the reduced possibility for the guanine oxidizing radical **42** to degrade **4** and also the presence of transition metals in

DNA. Both **4** and **49** were found to be generated in the DNA of human monocytes on exposure to γ rays and heavy ions^{109,110} at least partly according to the mechanisms depicted in Scheme 5. This was achieved using an accurate HPLC–MS/MS assay and a combined enzymatic/hydrolytic protocol that allows the quantitative release of **49** as a free base.¹⁴¹ An interesting feature of **49** is that it is generated in higher yield than **4**, whereas an opposite trend is noted in aerated aqueous solutions of isolated DNA. This may be explained by the lower concentration of O_2 and the presence of reducing agents in the nucleus. Further support for the predominant role of indirect effects in the radiation-induced degradation of cellular DNA is provided by the observation that an increase in linear energy transfer (LET) of $^{12}\text{C}^{6+}$ ($24.5 \text{ keV}/\mu\text{m}^{-1}$) and $^{36}\text{Ar}^{18+}$ ($250 \text{ keV}/\mu\text{m}^{-1}$) heavy ions with respect to γ photons leads to a decrease in the yield of both **4** and **49**. It may be added that **47**, the

main $\cdot\text{OH}$ -mediated degradation product of **1** in aerated aqueous solution has been detected by HPLC–MS/MS in the DNA of diabetic rats.¹⁴² It was proposed that the formation of **47** whose yield is about 10-fold lower than that of **4**, may be rationalized in terms of oxidative stress induced by diabetes with the concomitant release of $\text{O}_2^{\cdot-}$ and the subsequent generation of $\cdot\text{OH}$.

2.2.4 Adenine

4,6-Diamino-5-formamidopyrimidine (**52**) and 8-oxo-7,8-dihydro-2'-deoxyadenosine (**53**) have been shown to be the two main $\cdot\text{OH}$ -mediated degradation products of adenine (**50**) as free nucleosides^{143,144} and within isolated DNA⁵⁴ in aqueous solutions. The mechanism of formation of **52** and **53** which is similar to that of **49** and **4**, for the two guanine analogs, is depicted in Scheme 6. Addition of $\cdot\text{OH}$ at C8 of **50** gives rise to transient 8-hydroxy-7,8-dihydroadenyl **51**, which is subsequently converted into **52** and **53** on one-electron reduction and one-electron oxidation, respectively. A similar degradation pathway is likely to explain the radiation-induced formation of **52** and **53** in cellular DNA via the indirect effect of γ rays.^{109,110} It should be mentioned that the yields of **52** and **53** in both naked and cellular DNA are about 10-fold lower than those of **49** and **4**, respectively. This is likely due to the

enhancement of the formation of **4** and **49** as the result of efficient charge transfer reactions, guanine being the sink of positive holes, and the formation of tandem base lesions with the participation of vicinal pyrimidine peroxy radicals.¹⁴⁵ Application of the accurate HPLC–MS/MS method has allowed revisiting the $\cdot\text{OH}$ -induced chemical reactions of **50** in isolated and cellular DNA. Thus, the formation of 2-hydroxy-2'-deoxyadenosine was not detected in γ -irradiated human monocytes up to doses of 200 Gy¹⁴⁶ This contrasts with previous GC–MS measurements, which have shown that 2-hydroxy-2'-deoxyadenosine is one of the predominant $\cdot\text{OH}$ -mediated degradation products in the DNA of γ -irradiated cells and mice.^{147,148}

2.3 One-Electron Oxidation of Nucleobases

2.3.1 Thymine

A convenient and efficient method to induce one-electron transfer and generate pyrimidine radical cations in aerated aqueous solutions involves photosensitization with 2-methyl-1,4-naphthoquinone (MQ) on excitation by UVA radiation.¹⁰⁴ Using this approach, two main decomposition pathways of thymidine radical cations **55** have been identified^{24,149–151} (Scheme 7). The hydration of thymidine radical cations gives mainly

Scheme 6 $\cdot\text{OH}$ and one-electron oxidation reactions of adenine (**50**).

Scheme 7 One-electron oxidation reactions of thymine (**9**).

oxidizing 6-hydroxy-5,6-dihydrothymid-5-yl radicals (**11**) as inferred by spin trapping in electron spin resonance (ESR) experiments.¹⁵² These results were confirmed from the isolation of the four *cis* and *trans* diastereomers of 5-hydroperoxy-6-hydroxy-5,6-dihydrothymidine **16**^{150,151} (Scheme 2). The formation of stable thymidine degradation products including the four *cis* and *trans* diastereomers of 5,6-dihydroxy-5,6-dihydrothymidine (**19**), the 5*R** and 5*S** forms of 5-hydroxy-5-methylhydantoin (**22**), and formamide (**21**) nucleosides may be explained in part by thermal decomposition of hydroperoxides **16**. Altogether, the hydration pathway accounts for 60% of the total degradation products of isolated thymidine (**9**). The remaining stable products accounting for 40% of the total may be explained by the initial deprotonation of the thymidine radical cation **55** (Scheme 7). Interestingly, the relative importance of the two pathways is dependent on the photosensitizer used since deprotonation was significantly more favored on benzophenone-mediated photosensitization with UVA light compared to MQ-photosensitization. An influence of the pK_a of the radical anion of the sensitizer was proposed to account for this result.¹⁵³ Deprotonation of **55** gives rise to the allylic 5-methyl-(2'-deoxyuridylyl) radical (**12**).^{150,151} Efficient addition of O_2 to **12** is the first step of a sequence of reactions, that through the intermediacy of the corresponding peroxy radical **17** and its subsequent reduction, lead to the generation of highly stable 5-(hydroperoxymethyl)-2'-deoxyuridine (**18**) as the

precursor of **23** and **24**. The formation of the latter oxidized nucleosides may be also rationalized in terms of a Russell mechanism¹⁵⁴ in which the intermediate tetroxide **56** formed by combination of two 5-(hydroperoxymethyl)-2'-deoxyuridylyl radicals **17** decomposes with subsequent formation of alcohol **23** and aldehyde **24** products together with concomitant release of 1O_2 as recently proposed for the decomposition of peroxy radicals of linoleic acid.¹⁵⁵ Hydration and deprotonation reactions of **55** previously identified in 2'-deoxyribonucleosides (*vide supra*) have been shown to occur in isolated DNA and double-stranded oligonucleotides.^{156,157} This was achieved on suitable digestion of oxidized DNA to 2'-deoxyribonucleosides followed by HPLC to versatile and sensitive electrospray ionization MS/MS detection.⁵⁴ Thus, several oxidized nucleosides, including **19**, **23**, and **24** were generated in DNA and AT-containing oligonucleotides exposed to high-intensity UVC laser pulses^{27,149,156} and UVA excited anthraquinone,¹⁵⁷ respectively. It is interesting to note that, in the latter case, final damage was localized on thymine rather than on adenine, probably as the result of the higher reactivity of pyrimidine radical cations. Evidence for the one-electron oxidation-mediated formation of **23** and **24** in isolated DNA was gained from previous studies with menadione, riboflavin, and nitro derivatives of lysine, as type I photosensitizers.^{156,158} Interestingly, the formation of **19**, **23**, and **24** was observed in cellular DNA on exposure to high-intensity UVC laser pulses¹¹⁰

Scheme 8 One-electron oxidation reactions of cytosine (**25a**).

that have been able to photo-ionize pyrimidine and purine bases with a similar efficiency in isolated DNA.^{26,27}

2.3.2 Cytosine

The radical cation of cytosine **57** is efficiently generated in aqueous solution by near-UV photosensitization of the nucleoside with 2-methyl-1,4-naphthoquinone (menadione, MQ).¹⁰⁴ On the basis of product analyses, the mechanism of formation of stable products of cytosine nucleoside may be divided into two competitive reaction pathways: hydration (**57** → **26a** + **27a** where “a” refers to cytosine derivatives; Scheme 3) and deprotonation (**57** → **58** + **60**; Schemes 8). Hydration of **57** leads to cytosyl radicals (**26a** and **27a**), which are identical to those generated by the addition of $\cdot\text{OH}$ to cytosine. Thus, the majority of stable products for the nucleoside are the same from both $\cdot\text{OH}$ -induced reactions and one-electron oxidation. Experiments in the presence of $^{18}\text{O}_2$ showed that the label is incorporated at C5 and C6 of the pyrimidine ring in a ratio of about 40 and 60%, respectively, on the basis of MS analysis of products **33**, **34a**, and **21**.¹²² These results suggest that the addition of H_2O occurs with similar efficiency at both C5 and C6 positions of cytosine radical cations (**57**). The greater yield of imidazolidine products (**37a**) in the reactions of $\cdot\text{OH}$ with cytosine (**25a**) compared to the reaction of cytosine radical cations

(**57**) suggests that **37a** is more efficiently produced from 5-hydroxy-substituted 6-hydroperoxyl radicals (**28a**) and/or the corresponding hydroperoxides (**29a**) than from 6-hydroxy-substituted derivatives (**30a** or **31a**). The deprotonation of **57** leads to 2'-deoxyuridine (**59**) as the major product in the MQ-photosensitized oxidation of cytosine nucleoside (**25a**) (Scheme 8).¹²² The formation of cytosine N^4 -aminyl radicals (**58**) was confirmed by ESR experiments in the photosensitization of 1-methylcytosine by triplet anthraquinone-2,6-disulfonic acid (AQ).¹⁵⁹ From a computational perspective, the lowest free energy barrier pathway for deamination involves the addition of water to the N3–C4 imine bond followed by cleavage of the C4–N4 bond.¹⁶⁰ Finally, cytosine radical cation (**57**) also undergoes deprotonation from the C1' position of the sugar moiety (**57** → **61**) leading to the release of cytosine and 2-deoxyribo-1,4-lactone (**61**) in equal amounts.¹⁶¹

2.3.3 5-Methylcytosine

5-Methylcytosine (**25b**) is more susceptible to single electron oxidation because of its lower oxidation potential compared to both cytosine and thymine. Indeed, the formation of 5-methylcytosine radical cation (**62**) as monitored by electron paramagnetic resonance was favored upon irradiation of crystals of cytosine that contained small amounts of 5-methylcytosine as an impurity.^{162,163}

Scheme 9 One-electron oxidation reactions of 5-methylcytosine (**25b**).

Compound **25b** was also preferentially oxidized in oligonucleotides containing G by photosensitized electron transfer with naphthoquinone in aerated aqueous solutions.¹⁶⁴ The deprotonation of **62** to 5-methyl-(2'-deoxycytidylyl) radical (**63**) is a major reaction for the nucleoside in aqueous solution ($\sim 60\%$) (Scheme 9).¹²⁷ The methyl centered radical **63** likely transforms into the corresponding peroxy radical **64** and hydroperoxide **65** (half-life = 9.5 hours at 24°C). In turn, **65** can decompose into stable methyl oxidation products namely 5-(hydroxymethyl)-2'-deoxycytidine (**67**) and 5-formyl-2'-deoxycytidine (**68**) (Scheme 9). Interestingly, the one-electron oxidation of **25b** by UV photolysis of oligonucleotides tethered to naphthoquinone displayed an unusual pH dependence with a maximum production of **68** observed at pH 5–6 and lower yields at both extremes of pH (pH 4 and 8).¹⁶⁵ This phenomenon was explained by two competitive pathways: one involving deprotonation from the exocyclic amino group that cycles back to **25b**; and the other involving irreversible deprotonation from the methyl group leading to methyl oxidation products.¹⁶⁵ There is considerable interest today in the presence of **67** in cellular DNA because of its high levels (0.3–0.7% of cytosine) in brain and embryonic stem cells.^{166,167} In cells, the oxidation of **25b** may occur via Fe^{2+} -mediated oxidation of the methyl group by ten-eleven-translocation (TET) family enzymes.¹⁶⁸ This modification was previously shown to arise from the single electron oxidation of **25b** and subsequent deprotonation of the corresponding radical cation **62**.¹²⁷

2.3.4 Guanine

As observed for pyrimidine bases, deprotonation and hydration of the purine radical cations are the main competitive pathways that lead to the formation of several degradation products. Thus, one-electron oxidation of **1** gives rise to intermediate **69**, which undergoes deprotonation with a rate constant of $1.8 \times 10^7 \text{ s}^{-1}$ for the nucleoside¹⁶⁹ leading to the generation of oxidizing $\text{G}(-\text{H})^\bullet$ (**70**) (Scheme 10). The two predominant degradation products of the purine moiety of free 2'-deoxyguanosine (**1**) arising from the fate of **69** were identified as 2,2-diamino-4-[(2-deoxy- β -D-erythro-pentofuranosyl)amino]-5(2H)-oxazolone (**47**) and its precursor, 2-amino-5-[(2-deoxy- β -D-erythro-pentofuranosyl)amino]-4H-imidazol-4-one (**46**).^{129,130} The mechanism of their production as depicted in Scheme 4 has been rationalized in terms of multistep reactions of **70** or more likely of its isomeric C5 carbon-centered radical **42** that arises also from the initial 'OH -mediated hydrogen abstraction from the 2-amino group of **1** followed by tautomerization.¹⁶ Interestingly, the nucleophilic addition of a water molecule in the sequence of events leading to **47** has received support from the competitive formation of an anhydronucleoside on one-electron oxidation of **1**.¹⁷⁰ This constitutes a relevant model system for investigating the mechanism of oxidatively generated DNA–protein cross-links as proposed in the previous studies.^{171,172}

Scheme 10 Nucleophilic addition reactions at C8 of the guanine radical cation (**69**).

Hydration of **69** has been shown to lead to 8-hydroxy-7,8-dihydroguanyl radical **48** with a pseudo-first-order rate constant estimated to be $6 \times 10^4 \text{ s}^{-1}$ in dsDNA.¹⁷³ This was found to occur according to a counterion-assisted proton shuttle mechanism that was inferred from molecular dynamics and *ab initio* quantum simulations.¹⁷⁴ Evidence for the significant nucleophilic addition of H_2O to C8 of **69** in native calf thymus was provided by the incorporation of ^{18}O into **4** on riboflavin photosensitized oxidation reactions performed in H_2^{18}O solutions.¹⁷⁵ Two major competitive reactions of **48**, which are also generated by $\cdot\text{OH}$ ¹³⁶ (Scheme 4) have been shown to lead to **4** and **49** in a relative ratio that is strongly dependent on the redox status of the environment, and in particular, on the oxygenation of aqueous solutions. In this respect, product **4** is formed predominantly at the expense of **49** in aqueous solutions of dsDNA on one-electron oxidation.¹⁵⁶ This contrasts with the formation of only traces of **4**, which were detected on riboflavin-mediated photosensitized ionization of guanine (**1**) as the free 2'-deoxyribonucleoside.¹⁷⁶ This may be accounted for by an almost complete oxidation of **4** as soon as it is generated by the oxidizing $\text{G}(\text{-H})^\bullet$ radical **70** ($k = 0.46 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ at pH 7.0) derived from **1**.¹⁷⁷ Another explanation for the lack of **4** in single-stranded DNA (ssDNA) involves efficient deprotonation of **69**, which occurs more readily owing to the absence of base stacking and pairing.¹⁷⁵

Several interesting examples of nucleophilic addition reactions at C8 of **69** have become available more recently as illustrated by the isolation and characterization of novel guanine adducts. As a striking observation, a guanine-lysine cross-link **72** was generated on riboflavin photosensitization of the tight complex formed between TGT trinucleotide and KKK trilycine peptide.¹⁷⁸ This was rationalized in terms of efficient addition of the central lysine residue of KKK to C8 of **69** leading to transient **71** followed by a one-electron oxidation step as proposed from the formation of **4** from **48** (Scheme 10). The alternative mechanism of formation of **72**, in which the lysine radical cation adds to the guanine moiety appears to be less likely.¹⁷⁹ The guanine radical cation **69** is also implicated in the formation of cross-links with either thymine or uracil bases separated from the guanine moiety by cytosine in single-stranded oligonucleotides.^{180,181} A reasonable mechanism for the formation of the base adducts involves nucleophilic addition between the N3 position of pyrimidine bases and the C8 position of **69**.

A major difference between the chemistry of base radical cations as free nucleosides compared to those within dsDNA is the occurrence of efficient electron transfer along DNA strands leading to a redistribution of the initially generated base radical cations (see **Charge Transfer in DNA**). Several mechanisms of transfer including polaron-mediated hopping, two-step hopping with superexchange, and coherent long-range tunneling have been proposed.^{182–185} This leads to

damage at a distance, mostly at guanines and to a lesser extent at adenines, from the initial site of radical cation generation.²⁶ This may be accounted for by the fact that guanine (**1**) bases have the lowest oxidation potential, and thus, act as preferential sinks for positive hole migration. On the basis of both experimental and theoretical investigations, intra- but not interstrand charge migration was shown to be implicated in the formation of damage at **1** following 193 nm laser pulse-mediated one-electron oxidation of nucleobases in dsDNA.¹⁸⁶ Kinetic information has been gained on the two competitive reactions of guanine radical cation **69**, namely hydration and hole transfer to other guanine sites.¹⁷³ Thus, the pseudo-order rate for the hydration of **69** was estimated to be about $6 \times 10^4 \text{ s}^{-1}$, a value that is two orders of magnitude lower than that of hole migration between two isolated guanines separated by two AT base pairs.¹⁷³

Evidence for hole transfer reactions within cellular DNA has been provided from the HPLC–MS/MS measurements of the preferential formation of **4** at the expense of thymidine oxidation products including **19**, **23**, and **24** in human cells on exposure to high-intensity UVC nanosecond laser pulses. A comparison of the product distribution obtained following ionization of DNA bases and that obtained on exposure to γ rays indicates the major contribution of the indirect effect mediated by $\cdot\text{OH}$ under the latter conditions.¹¹⁰

2.3.5 Adenine

One-electron oxidation reactions of adenine (**50**) in free nucleosides have been shown to lead to the formation of 8-hydroxy-7,8-dihydroadenyl radicals (**51**) through hydration of the initially generated adenine radical cation **54** (Scheme 6). In addition, competitive deprotonation of **54** gives rise to oxidizing the 6-aminyl radical, which is the likely precursor of hypoxanthine on deamination.^{187–189} The reducing radical **51** is able, as already discussed in Section 2.2.4, to undergo two competitive reactions in aqueous solutions. One-electron oxidation of **51**, mostly by molecular oxygen, gives rise to 8-oxo-7,8-dihydroadenine (**53**), whereas one-electron reduction leads to 4,6-diamino-5-formamidopyrimidine (**52**) through the transient formation of 8-hydroxy-

7,8-dihydroadenine.^{143,144} A similar degradation pathway would explain the formation of both **52** and **53** in the DNA of human THP1 cells on exposure to high-intensity nanosecond UVC laser pulses.¹¹⁰

2.4 Secondary Oxidation Lesions

2.4.1 8-Oxo-7,8-dihydroguanine

8-Oxo-7,8-dihydro-2'-deoxyguanosine (**4**) has been shown to be more susceptible to several oxidizing agents including $^1\text{O}_2$ and one-electron oxidants than the parent compound **1**.^{24,190} In that respect, it was found that the rate of reaction of $^1\text{O}_2$ with **4** is about two orders of magnitude higher than that with **1**.^{191,192} The reaction of $^1\text{O}_2$ with free nucleoside **4** predominantly leads to the formation of cyanuric acid together with 2,2,4-triamino-5-(2*H*)-oxazolone (**47**) and the 4*R** and 4*S** diastereomers of **8**.^{68,193–195} This is likely to be explained in terms of $^1\text{O}_2$ addition across the 4,5-ethylenic bond of **4** to yield the transient dioxetane **73**. The $^1\text{O}_2$ -mediated oxidation of **4** inserted within a single-stranded oligonucleotide was found to be more specific. Oxaluric acid (**77**) was the overwhelming $^1\text{O}_2$ oxidation product.¹⁹⁶ This was rationalized by the initial formation of dioxetane **73** on $^1\text{O}_2$ addition across the 4,5-ethylenic bond¹⁹⁰ followed by rearrangement into the transient **74** (Scheme 11). At this point, hydroperoxide **74** may be converted into a derivative of dehydro-guanidinohydantoin **75** after cleavage of the 5,6-bond and subsequent decarboxylation. The final degradation steps involve two successive hydrolytic steps that lead to the formation of **77** through transient parabanic acid (**76**). It may be pointed out that **75** is stable enough for its characterization, and therefore, it has been generated by two electron oxidation of guanine within d(GpT) using the Mn-TMPyp/KHSO₅ oxidizing system.¹⁹⁷

There are numerous examples showing that **4** whose oxidation potential is about 0.5 eV lower than that **1**¹⁹² is a preferential target for a large number of one-electron oxidants. These oxidants include Na₂IrCl₆, K₃Fe(CN)₆, CoCl₂/KHSO₅, high-valent chromium complexes, peroxy radicals, triplet ketones, oxyl radicals, ionizing radiation through the direct effect, and riboflavin.²⁴ The

Scheme 11 $^1\text{O}_2$ oxidation reactions of 8-oxo-7,8-dihydroguanine (**4**) in oligonucleotides.

one-electron oxidative degradation pathway of **4** (Scheme 11) involves the transient formation of 5-hydroxy-8-oxo-7,8-dihydroguanine (**7**) through a still not completely elucidated mechanism after the initial formation of radical cation **78**. The rearrangement of **7** into the two diastereomers of **8** through an acyl shift was found to be favored in neutral and slightly alkaline aqueous solutions in the case of isolated nucleosides.^{79, 198–200} At pH lower than 6.5, a different decomposition pathway of **7** takes place by initial opening of the 5,6-pyrimidine ring followed by a decarboxylation reaction to give two diastereomers of guanidinohydantoin derivatives **79**.²⁰¹ Oxazalone nucleoside **47** together with its imidazolone **46** precursor was also found to be one-electron oxidation products of **4**, although generated in lower yields than **8** and **79**.²⁰² It is worth mentioning that **8** is preferentially formed in ssDNA, whereas the generation of **79** is favored in duplex DNA.²⁰¹

Two diastereomers of **8** were reported to accumulate in the DNA of Nei deficient *Escherichia coli* cells on exposure to chromate ion.²⁰³ The frequency of **8**, assessed by HPLC–MS operating in the selective ion monitoring (SIM) mode, was estimated to be 6 lesions per 10^3 guanines on treatment of TK3D11 bacterial cells with $500\ \mu\text{M}$ Cr(VI); this frequency is about 20-fold higher than that observed in the wild-type cells. It is intriguing that in both bacterial cells, the level of **4**, which is the likely precursor of **8**, is much lower. Other questionable issues

include the lack of accuracy of HPLC–MS for measuring low levels of base modifications⁵⁸ and the fact that **8** is formed only in ssDNA.²⁰¹ One may add that the proposed sacrificial role of **4** in protecting normal nucleobases within DNA against the damaging effects of one-electron oxidants^{204,205} has been recently questioned.²⁰⁶ This raises the question of how **4**, whose endogenously generated steady-state level does not exceed at best a few residues per 10^6 , can preferentially undergo one-electron oxidation in the presence of an overwhelming amount of **1** if one considers that hole transfer process within DNA helix does not likely occur at distances greater than 20 bp.

2.4.2 5-Hydroxypyrimidine Bases

The nucleosides of 5-hydroxycytosine (**33**) and 5-hydroxyuracil (**35**) are susceptible to secondary oxidation because of their relatively low oxidation potential. The oxidation potential of **33** is 70 mV, while that of **35** is 150 mV, versus the Pd reference electrode (in comparison, the oxidation of normal DNA bases is higher than 700 mV).^{117,120} Oxidation of **35** by either Br_2 or Na_2IrCl_6 leads to the quantitative formation of isodialuric acid (**35** $\rightarrow$ **80**; Scheme 12).^{206,207} Remarkably, the decomposition of **80** involved a sequence of three transformations in which

Scheme 12 One-electron oxidation reactions of 5-hydroxyuracil (**35**).

each product in the sequence (**80**, **81**, **40**, **82**) existed as a pair of diastereomers. After 2 hours at 37 °C in neutral aqueous solution, **80** transformed in a stereospecific manner into the corresponding dialuric acid product **81**. Both **80** and **81** assumed a fully hydrated hemiacetal form in aqueous solution as determined by NMR and MS. Further incubation at 37 °C for 72 hours resulted in the transformation of **81** into a mixture of four products consisting of two diastereomers of 5-hydroxyhydantoin (**40**) and two diastereomers of 5-hydroxy-3-methylimidazolidine-2,4-dione (**82**). The mechanism of decomposition of **81** probably involves initial ring-opening between N1–C6 followed by decarboxylation of an intermediate ureid. The four products likely interconvert by α -hydroxyketone rearrangement (**40** $\rightarrow$ **82**; half-life = 80–120 hours) accompanied with slow ring-chain tautomerism (12-fold slower than rearrangement), which accounts for the conversion between the diastereomers of **40** (tautomerism at N1–C5) and the diastereomers of **82** (tautomerism at N3–C4). In comparison, the oxidation of **33** by Br₂ resulted in the formation of analogous products (**80** and **81**) except that they retained the exocyclic amino group. These results indicate that the deamination of intermediate products (i.e., analogous to **80** and **81**) derived from **33** takes place on the same timescale as the decomposition of **80** and **81** (several hours).²⁰⁷ The treatment of trimers as well as longer oligonucleotides (<15 mer) containing **35** with Na₂IrCl₆ led to the quantitative formation of **80** within the oligomer as inferred by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) analysis.²⁰⁸ Interestingly, whereas the fully hydrated form of **80** existed as a free nucleoside in aqueous solution, the dehydrated carbonyl form appeared to prevail in single-stranded oligomers.

3 TANDEM BASE LESIONS

The pioneering work of Box and coworkers^{209–212} has highlighted the importance of the so-called tandem damage involving the formation of two adjacent DNA modifications. Formation of such damage is initiated by a single ionization event generating a single radical, which in oligonucleotides or DNA can react with neighboring bases creating the so-called tandem lesions constituted of two (at least) adjacent modifications. Indirectly, such an observation indicates that decomposition of initially produced base (or sugar) radicals may be influenced by their local environment, and thus, the decomposition reactions observed at the nucleoside level may be different, at least partly, in comparison to those in dsDNA.

3.1 Intrastrand Pyrimidine–Purine Cross-Links

Under anoxic conditions, Box and coworkers showed that tandem lesions involving intrastrand bases cross-links were produced in significant amounts in short oligonucleotides exposed to $\cdot\text{OH}$ generated by the radiolysis of aqueous solutions.²¹¹ Most of the lesions involved formation of a cross-link between a pyrimidine and a purine base, and among these, the majority of lesions implicated either the formation of a bond between the C8 of guanine and the C5 of a pyrimidine (with or without saturation of the C5–C6 double bond) or the exocyclic methyl group of thymine. Additional studies confirmed that such tandem lesions were generated in dsDNA exposed to ionizing radiation, and they were also detected in cells (Scheme 13). A detailed study²¹³ with tandem lesions involving a cross-link between the C8 of purines (for both adenine and guanine) and the methyl group of thymine showed that cross-links involving the guanine base

Scheme 13 Adenine–thymine (**83**) and guanine–cytosine (**84**) tandem lesions formed by initial $\cdot\text{OH}$ reactions on the pyrimidine moiety.

predominate in dsDNA. In addition, there was a strong sequence effect such that the adducts were generated most efficiently when the purine base was located 3' to thymine giving the so-called G[8-5 m]T **83** tandem lesion. The proposed mechanism of formation of such a lesion involved the formation of methyl radicals (**12**), which in turn add to the C8 of an adjacent purine base. The addition of methyl radicals is favored when the purine base is located 5' to the pyrimidine base since the distance between the radical (**12**) and the C8 of purines is shorter in the latter sequence, compared to the opposite one. Using HPLC–ESI–MS/MS, G[8-5 m]T (**83**) and G[8-5]C (**84**) were quantified in cells exposed to ionizing radiation.^{214,215} However, the yield of formation of such adducts was found to be significantly lower compared to that of single lesions including **4** and **24**. Indeed, the yield of formation of **84** was estimated to be around 0.037 lesions per 10^9 nucleosides per Gy, which is about 2–3 orders of magnitude lower than the reported yield of single lesions.

3.2 Lesions Involving Pyrimidine Hydroperoxyl Radicals

The low yield of formation of intrastrand cross-links between adjacent DNA bases may be explained, at least partly by the efficient competitive reaction of O_2 with the initially produced C-centered radicals. Interestingly, the generated peroxy radicals have been also shown to be able to produce tandem DNA lesions generating two adjacent oxidatively generated DNA lesions. With

dinucleoside monophosphates, Box and coworkers identified radiation-induced tandem lesions containing a formylamine (**21**) residue linked to **4**,²⁰⁹ the so-called 8-oxo-7,8-dihydroguanine/formylamine (8-oxodGuo/dF) lesion.¹³² Additional work performed on isolated dsDNA has provided a clear explanation for the mechanism of formation of this tandem lesion.^{216,217} Similarly, as reported for pyrimidine–purine cross-links, a strong sequence effect was observed since 8-oxodGuo/dF was found to be generated in higher amounts (about 20 times) compared to the opposite sequence dF/8-oxodGuo. Using ^{18}O -labeling, the tandem lesion was clearly shown to arise from the initial formation of 6-hydroxy-5,6-dihydrothymine-5-yl radicals (**86**) and, after the addition of molecular oxygen, the corresponding peroxy radicals in GpT (**87**; Scheme 14).¹³³ A key step is the addition of peroxy radicals (**87**) onto the C8 position of guanine to generate an intermediate endoperoxide (**88**), which decomposes to give two vicinal DNA lesions (**89**; 8-oxodGuo **4** adjacent to formylamine (**21**)) as well as several others (**90**; where X is an oxidation product of thymine or cytosine; *vide infra*). The formation of tandem lesions (**89** and **90**) is not a minor process since they represent about 15% of the total amount of generated **4** and additional results suggested the formation of other tandem lesions containing unidentified pyrimidine modifications **90** together with 8-oxodGuo **4**.

The yield of tandem lesions in dsDNA exposed to ionizing radiation in aqueous aerated solutions is estimated to be about 50% of the total amount of generated **4**.¹⁴⁵ Using polynucleotides containing specific DNA bases and an isotope-based

Scheme 14 Formation of tandem bases lesions between 3'-thymine and 5'-guanine arising from initial $\cdot\text{OH}$ addition across the 5,6-pyrimidine bond.

methodology, it was shown that pyrimidine peroxy radicals **13** and **15** are able to add to the C8 position of both guanine and adenine, but only when the purine bases are located on the same strand as the pyrimidine bases, thus generating tandem lesions containing oxidized purine bases such as either 8-oxodGuo **4** or 8-oxo-7,8-dihydro-2'-deoxyadenosine (**53**). It was determined that 50% of **53** is generated by a mechanism involving in tandem lesions, whereas the other 50% may be expected to arise by the direct addition of $\cdot\text{OH}$ produced by water radiolysis to the C8 of adenine (**50**). In dsDNA, three main mechanisms are involved in the formation of **4**. Interestingly, the addition of $\cdot\text{OH}$ to C8 of **1** (Scheme 5), which is the main reaction at the nucleoside level, accounted for only 5% of the generated **4**. As reported for **53**, 50% of the generated **4** is produced by the addition of a pyrimidine peroxy radical onto C8 of **1**, thereby generating 8-oxodGuo **4** containing tandem lesions (**89** + **90**). Of further interest, the remaining 45% of $\cdot\text{OH}$ -induced **4** was found to be produced by a one-electron oxidation mechanism, probably also involving peroxy radicals, a mechanism that favors

the formation of **4** compared to **53** likely due to the lower ionization potential of guanine and efficient electron transport of base radical cations in dsDNA to **1**. This provides an explanation for the higher formation yield (by about one order of magnitude) of **4** compared to that of **53** in dsDNA exposed to ionizing radiation. Work is in progress in order to identify the main pyrimidine modifications adjacent to **4** in tandem lesions **90** (Scheme 14). This is important because **4** within tandem lesions has been shown to be significantly refractory to repair by DNA glycosylases such as either the bacterial Fpg protein or human hOGG1.¹⁴⁵ Indeed, a high proportion of **4** involved in tandem lesions was resistant to excision by these two DNA glycosylases. Efficacy of excision may depend on both the sequence and on the nature of pyrimidine modifications adjacent to 8-oxodGuo **4** in **90**. Indeed, the presence of **21** does not significantly affect Fpg protein activity,²¹⁶ whereas the cleavage of **4** was considerably compromised by the presence of a 5' neighboring **19** (Scheme 2). In contrast, the presence of **19** as an adjacent 3' nucleoside enhanced **4** cleavage by hOGG1.^{217,218} It should also be taken into account

that tandem lesions containing two pyrimidine modifications may be generated through similar mechanisms involving the addition of peroxy radicals onto adjacent pyrimidine bases.²¹⁹

4 OTHER COMPLEX LESIONS

Other complex DNA lesions have been identified and quantified in DNA. Formation of such lesions arose from the initial formation of sugar radicals which, following different pathways, leads to different types of lesions involving purine 5',8-cyclonucleosides and several base-to-sugar adducts derived from the transient formation of reactive aldehydes.

4.1 Cytosine Adducts Arising from C4' Radical

Following an attempt to search for the radiation-induced formation of novel DNA lesions,²²⁰ high molecular weight modifications were detected in the DNA of THP1 cells exposed to ionizing radiation, or to bleomycin, a radiomimetic drug. Identification of these lesions,²²¹ consisting of four diastereomers, revealed that these are cytosine adducts. The mechanism of their formation involves a complex cascade of events initiated by C4' hydrogen abstraction on the 2-deoxyribose moiety (**91**) in dsDNA (Scheme 15). Reaction of the C4' centered radical (**92**) with molecular oxygen gives rise to a C4' oxidized abasic site **93**, which may exist in a dynamic equilibrium with the open form **94**. Following β -elimination, the keto-aldehyde thereby generated **95** is able to react with a surrounding cytosine base (**25a**) producing the four diastereomers of 6-(2-deoxy- β -D-*erythro*-pentofuranosyl)-2-hydroxy-3-(3-hydroxy-2-oxopropyl)-2,6-dihydroimidazo[1,2-c]-pyrimidin-5(3*H*)-one, which exist in either an open chain (**96**) or closed ring (**97**) probably depending on the stereochemistry of the isomers. Interestingly, using a photochemical precursor of C4' oxidized abasic site **93**, Greenberg's group²²² has shown that the reaction of aldehyde **94** occurs preferably with a cytosine base (**25a**) located onto the opposite strand.²²³ Therefore, the unusual complex lesion **97** involves a strand break together with an interstrand cross-link. Moreover, it can

not be excluded that the reactive aldehyde **94** may also react with other DNA constituents containing nucleophilic amino groups such as the purine bases, creating similar types of complex lesions. Indeed, it was recently shown that the reaction of nucleophilic amino acids with the above-mentioned aldehyde **94** can also give rise to the formation of DNA-protein cross-links.²²⁴ In cells, the yield of radiation-induced formation of **97** was found to be similar to that of double-strand breaks.²²¹ In view of the relatively slow kinetics of removal of **97** from cellular DNA (half-life of about 10 hours), the DNA repair of **97** probably involves nucleotide excision repair rather than base excision repair that removes single lesions. In addition, the repair of such complex damage by the UvrABC nucleotide excision repair system was found to give rise to double-strand breaks.²²⁵ It should also be mentioned that following the generation of abasic sites on spontaneous depurination, the formation of adducts with cytosine have also been reported²²⁶ highlighting the importance of such nucleophilic reactions of DNA bases with transiently produced aldehydes to generate complex DNA lesions.

4.2 Purine 5',8-cyclonucleosides

The initial step in the formation of 5',8-cyclonucleosides (Scheme 16) involves $\cdot\text{OH}$ -mediated generation of C5' radical followed by intramolecular addition onto C8 of the purine base.^{36,40,227} Detailed information on the mechanism of formation of such complex DNA lesions including those derived from both adenine (**98**) and guanine (**99**), as well as on their relative importance has been reviewed recently.⁴⁰ The radiation-induced yield of such damage in isolated dsDNA was inversely correlated with the oxygen content because O_2 can trap C5' radicals and divert the reaction pathway to other products. During the last decade, several attempts were made to determine whether such complex DNA lesions including both **98** and **99** can be generated in significant amounts in cellular DNA. Since these unusual lesions are refractory to removal by base excision repair,^{228,229} it was proposed that **98** and **99** may accumulate in nucleotide excision repair (NER) deficient cells, and thus, be implicated in biological disorders observed in patients with Xeroderma pigmentosum (XP). Earlier determinations

Scheme 15 Formation of intrastrand cross-links (97) involving cytosine and the 2-deoxyribose through initial $\cdot\text{OH}$ -mediated hydrogen abstraction at C4'.

Scheme 16 (5'R)-5',8-cyclo-2'-Deoxyadenosine (**98**) and (5'S)-5',8-cyclo-2'-deoxyguanosine (**99**) formed by initial $\cdot\text{OH}$ -mediated hydrogen abstraction at C5'.

of the cellular level of **98** and **99** obtained by GC-MS and HPLC-MS (single MS) have given elevated levels of the purine 5',8-cyclonucleosides in control and γ -irradiated cells.^{230,231} Using a more accurate tandem mass spectrometry approach, it was found that the radiation-induced yield of these cyclonucleosides is significantly lower²³² than previously reported^{230,231} and even not detectable in untreated cells. It was estimated that the endogenous steady-state level of either **98** or **99** is below 1 modification per 10^9 normal bases. However, in a recent study using a HPLC-MS³ approach, the background level of **98** and **99** in rat tissues was determined to be about 0.1 lesion per million nucleosides.⁵⁷ Therefore, additional work is required to circumvent this apparent discrepancy, and the reported results highlighting the possible biological importance of this damage should be considered at the moment with caution.^{40,232}

5 CONCLUSIONS

In the last decade, there has been major progress toward elucidating the mechanisms of formation of oxidatively generated damage in isolated DNA and model compounds. In particular, there have been significant advances with single-oxidized nucleosides formed on exposure to $\cdot\text{OH}$, one-electron oxidants, and singlet oxygen. Evidence has been provided for the occurrence of tandem base modifications that are mostly induced next to either 5'-guanine or 5'-thymine by pyrimidine peroxy radicals on the 3' end. Other complex lesions arise from the nucleophilic addition of lysine residues and

opposite cytosine with guanine radical cations giving rise to DNA-protein adducts and intrastrand DNA cross-links. In addition, evidence has been provided for the formation of complex damage between cytosine and reactive aldehydes derived from initial oxidation of the 2-deoxyribose moiety. The development of accurate analytical methods such as HPLC-MS/MS has permitted the measurement of 14 single and complex oxidatively generated base lesions in cellular DNA. It is expected that the oxidation products of cytosine, tandem lesions, and DNA-protein cross-links will be the subjects of further investigations at the cellular level.

Oxidatively Formed Sugar Radicals in Nucleic Acids

Thanasis Gimisis¹ and Chrysostomos Chatgililoglu²

¹Department of Chemistry, National & Kapodistrian University of Athens, Panepistimiopolis, Athens, Greece and ²ISOF, Consiglio Nazionale delle Ricerche, Bologna, Italy

1 INTRODUCTION

Chemical modifications of DNA in the form of strand breaks and nucleobase modifications are known to be caused by reactive oxygen species (ROS), in particular the $\cdot\text{OH}$ radicals derived from the metabolism of oxygen.¹ However, the majority of cells also possess defense mechanisms against oxidative damage, such as base excision repair (BER) and nucleotide excision repair (NER) enzymes, which remove these lesions to maintain the integrity of the genome.² As a result of poorly repaired oxidative damage, some lesions may accumulate in cells over time through errors in repair, replication, and recombination, and the levels of repair proteins may decrease with the cell aging.³ In addition to the DNA damage caused by the metabolism of oxygen, damage may also be induced through other environmental insults such as ionizing radiation, UV light, and chemical mutagens. Although the majority of DNA lesions induced through oxidative metabolism are single lesions, there are also types of multiple lesions such as tandem DNA lesions and clustered DNA damage that may challenge the repair machinery of the cell.

Diffusible hydroxyl radicals ($\text{HO}\cdot$) are known to react with DNA either by hydrogen abstraction from the 2-deoxyribose units or, more often, by addition to the base moieties (see **Oxidatively**

Generated Nucleobase Modifications in Isolated and Cellular DNA). However, there is growing evidence that the oxidation of 2-deoxyribose in DNA plays a critical role in the genetic toxicology of oxidative stress and inflammation.⁴

There are five sp^3 -hybridized carbons on a 2'-deoxyribose residue containing seven hydrogen atoms that are, in theory, available for abstraction by an oxidizing agent. The hydrogens are designated (IUPAC rules) as H-5', H-5'', H-4', H-3', H-2', H-2'', and H-1', although the designation H-2' β and H-2' α (above and below the sugar plane, respectively) is frequently adopted for the 2'-hydrogens. X-ray crystallographic data from oligonucleotide duplexes indicate that H-5', H-5'', H-4', H-2' α , and H-1' are accessible from the minor groove, whereas H-3' and H-2' β are accessible from the major groove of a typical B-form duplex DNA (Figure 1). It is apparent from Figure 1 that H-5'' and H-4' are the most solvent-accessible hydrogen atoms within B-form duplex DNA.

The relative reactivity of a diffusible reactive species, such as the $\text{HO}\cdot$ radical, toward the various hydrogen atoms of the 2-deoxyribose moiety is generally accepted to follow the order of the 2-deoxyribose hydrogen atom exposure to solvent (i.e., $\text{H5}' > \text{H4}' > \text{H3}' \approx \text{H2}' \approx \text{H1}'$),⁶ although this is currently under debate.⁴ Experimental data on the reaction of $\text{HO}\cdot$ radicals with simple nucleosides such as 2'-deoxyadenosine and 2'-deoxyguanosine indicate that $\sim 25\%$ of H-atom abstraction occurs

Figure 1 An AT pair within a B-form double DNA helix. The hydrogens directed toward the viewer point toward the minor groove (between the orange ribbons), whereas the hydrogens directed away from the viewer point toward the major groove. The methyl group proton (CH_3), also pointing toward the major groove, belongs to the thymine base directed toward the back. This image was prepared with PyMol and contains a typical B-form double helix oligomer from the Protein Data Base (3EIL).⁵

at the sugar moiety, $\sim 40\%$ of which is at the $\text{H5}'$ position.⁷ On the other hand, $\text{C1}'$ -, $\text{C4}'$ -, and $\text{C5}'$ -hydrogen atoms are abstracted by several minor groove-binding molecules.^{8–10}

Abstraction of a hydrogen atom from 2-deoxyribose produces a carbon-centered radical whose fate depends upon the environment. Recent studies emphasize the selective generation of these species that allow quantitative data to be obtained. While the chemistry of all possible sugar radicals (i.e., $\text{C1}'$, $\text{C2}'$, $\text{C3}'$, $\text{C4}'$, and $\text{C5}'$) from nucleosides to DNA are discussed in this article, only the literature from the last decade is discussed in depth, with support from seminal work. The reader is referred to some excellent reviews^{8–14} and books^{15–17} for more details of earlier work. The chemistry of 2-deoxyribose oxidation in DNA was first addressed in studies of the effects of ionizing radiation on DNA, as summarized in two books by von Sonntag.^{15,16}

2 OXIDATION OF THE $\text{C5}'$ POSITION

2.1 Generation of the $\text{C5}'$ Radical

The chemistry of the $\text{C5}'$ radical **1** (Scheme 1) was one of the first to be studied in detail.⁸ Both $\text{C5}'$ hydrogens are the most accessible from the minor groove in B-DNA, one of which points

away from the groove toward the solvent.^{18,19} As a result, diffusible species such as the hydroxyl radical $\cdot\text{OH}$ generated by Fenton chemistry or gamma radiolysis, or the hydroperoxyl radical $\cdot\text{OOH}$,²⁰ has been reported to preferentially oxidize the $\text{C5}'$ position.²¹ On the other hand, other metal complexes, such as $\text{Cu}(\text{phen})_2$ derivatives²² or $\text{Mn}(\text{TMPyP})/\text{KHSO}_5$,^{23,24} which do not produce diffusible species, have exhibited $\text{C5}'$ oxidation chemistry. Finally, enediyne derivatives, such as neocarzinostatin, which are known to bind in the minor groove of DNA, produce this type of oxidation with some sequence selectivity.⁸

2.2 Fate of the $\text{C5}'$ Radical

The chemistry of the $\text{C5}'$ radical is peculiar compared to that of the other 2-deoxyribose positions since (i) the peroxy radical **2** does not generate an abasic site, which is interesting in the polymerase bypass and mutagenesis,⁴ and (ii) unique cyclic base-sugar adducts are formed (Scheme 1). For example, the 5',8-cyclo-2'-deoxyadenosine and 5',8-cyclo-2'-deoxyguanosine moieties, generally referred to as 5',8-cyclopurines, are the result of the $\text{C5}'$ radical attack at the purine moiety to give **3** more rapidly than its reaction with oxygen. These lesions are observed among the DNA modifications^{25,26} and have also been identified in mammalian cellular DNA *in vivo*.^{27,28}

2-phosphoryl-1,4-dioxo butane residue **8** represents a second lesion produced in lower yield by the cleavage of the C4'–C5' bond. Several mechanistic aspects of the 5'-oxidation pathways under aerobic conditions are not well understood. All the proposed intermediates are based on rationalization of the products observed in DNA degradation by neocarcinostatin chromophore (NCS-Chrom) in the

A 5'-aldehyde-terminated DNA, or oligonucleotide **13**, has been observed during the analysis of DNA oxidized by chemical nucleases such as Mn(TMPyP)/KHSO₅^{23,24} or natural products such as enediyne compounds⁸ (Scheme 2). The

presence of glutathione (**4**).^{8,9,12} The forming C5' radical **6** (where B = thymine) reacts with oxygen to generate the peroxy radical **7**, which should partition between two reaction channels to give the corresponding hydroperoxide after reaction with glutathione (GSH) (**4**) and the corresponding alkoxy radical by disproportionation. The hydroperoxide produces the 5'-aldehyde terminus **13** and fragment **12**, while the alkoxy intermediate could be responsible for the 3'-formyl phosphate residue **9** and the 5'-(2-phosphoryl-1,4-dioxobutane) residue **8** with the concomitant loss of base (Scheme 2). In other studies, a 5'-aldehyde-terminated oligonucleotide, resulting from the C5' hydroxylation of a 2-deoxyribose, led to **11**, where B is guanine.²⁹ This hydroxylation favors the spontaneous elimination of the attached phosphate group and the cleavage of DNA accompanied by the formation of the two DNA components, a 5'-aldehyde end (**13**) and a 3'-phosphate end (**12**).

Upon heating at 90 °C for 30 min or with alkaline treatment, the 5'-aldehyde **13** undergoes β,δ -elimination reactions with the release of furfural **14** and of the corresponding nucleobase, resulting in the formation of a one-nucleotide shorter 5'-phosphate DNA fragment (**15**, Scheme 2).²⁹ Furthermore, the 5'-aldehyde **13** is found to give adducts with nucleophiles.

The 5'-(2-phosphoryl-1,4-dioxobutane) residue **8** may exist in a hydrated form, which is expected to be in equilibrium with the cyclic form **16** (Scheme 3). The dialdehydic structure and β -elimination reaction that gives *trans*-1,4-dioxo-2-butene **17** and 5'-phosphate-terminated oligomers **15** were investigated in detail,^{30,31} and two analytical methods were developed for their detection and quantification of **17**.³⁰ It was recently shown that **17** forms adducts with dA and dC in oxidized DNA.³¹

The synthesis of oligonucleotides containing 5'-aldehyde or 2-phosphoryl-1,4-dioxo butane termini, resulting from the C5'-oxidation of thymidine in DNA, has been performed and the cleavage labilities of these species have been determined.³² Unlike thymidine, 5'-aldehyde **13** does not destabilize duplex DNA, whereas **8** affects the thermal stability of a duplex to an extent similar to that of a tetrahydrofuran model of an abasic site.

The reactivity of purine-substituted C5' radicals **18** under aerobic conditions has also been studied in some detail (Scheme 4).⁷ Using a 13–266 μ M

Scheme 3 Hydration and decomposition of the 5'-(2-phosphoryl-1,4-dioxobutane) fragment **8**.

oxygen concentration (typical for oxygenated tissues), the hydrated 5'-aldehyde **22** is accompanied by a 5',8-cyclopurine nucleoside (Figure 2). 5',8-Cyclopurine formation (see Section 2.2.2) was observed in all experiments, and the yields increased with decreasing O₂ concentration. The proposed mechanism involving the formation of peroxy radical **19**, which decays either via a cyclic transition state leading to HOO[•] radical and aldehyde **20** or via heterolytic cleavage to generate carbocation **21** and superoxide radical anion, is given in Scheme 4. The two pathways are formally identical. Trapping C5' radicals with Fe(CN)₆³⁻ gave the corresponding hydrated 5'-aldehydes **22** in good yield (Scheme 4).⁷ Similar experiments and results were reported for the 2'-deoxyinosin-5'-yl radical.⁷

2.2.2 Fate of the C5' Radical under Anaerobic Conditions: 5',8-Cyclopurines

The classic 5'-*tert*-butyl ketone modification for the site-specific generation of model sugar radicals, which was initially developed by Giese and coworkers in their studies of C4' radical chemistry (see below),^{33,34} has recently been extended to the C5' position. Photolysis of derivatives **27** and **30** leads to the formation of thymidin-5'-yl (**28**) and 2'-deoxyguanosin-5'-yl (**31**) radicals, respectively (Schemes 5 and 6).³⁵ In the thymidine system, the C5' radical **28** is fully quenched to give **29** in the presence of physiological concentrations of thiols. In the 2'-deoxyguanosine system, the C5' radical **31** is partially quenched to give **32** and undergoes competitive intramolecular attack onto

Scheme 4 Fate of the C5' radical in purine nucleosides.

Figure 2 Structures of four possible 5',8-cyclopurine nucleoside diastereomers.

the C8–N7 double bond of guanine, leading ultimately to the 5',8-cyclo-2'-deoxyguanosine derivative **34**. The **30** $\rightarrow$ **33** cyclization occurs with a rate constant of circa $1 \times 10^6 \text{ s}^{-1}$ (based on $k_H = 5 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$) and is highly stereoselective, affording only the (5'S)-isomer.

Both 5',8-cyclo-2'-deoxyadenosine (**23**, **24**) and 5',8-cyclo-2'-deoxyguanosine (**25**, **26**) have two diastereoisomeric forms, the (5'S) and (5'R)

isomers, which differ in the C5' position configuration (Figure 2). Both the 5'S and 5'R forms have been synthesized and fully characterized. The first report involves a multistep synthesis but in overall poor yield.^{36,37} A one-pot synthesis was developed starting from the commercially available 8-bromopurine derivatives under continuous radiolysis or photolysis,^{38–42} featuring a radical cascade reaction that mimics the DNA damage leading to these lesions. The mechanism of these reactions was investigated by time-resolved spectroscopy to provide important information on the fate of C5' radicals.^{39,40} Some of these findings are summarized in Scheme 7. Specifically, 8-bromo-2'-deoxyadenosine **35** captures electrons and rapidly loses a bromide ion to give the corresponding C8 radical **36**.³⁹ Radical **36** can also be obtained by homolytic cleavage of C–Br bond under photolysis.⁴⁰ This intermediate intramolecularly abstracts a hydrogen atom selectively from the C5' position to give the 2'-deoxyadenosin-5'-yl radical **37**, which can undergo cyclization with a rate constant of $k_c = 1.6 \times 10^5 \text{ s}^{-1}$ to produce the heteroaromatic radical **38**. The reactivity of the C5' radical **37** toward GSH ($k = 4.9 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$), O_2 ($1.8 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$), and $\text{K}_3\text{Fe}(\text{CN})_6$ ($4.2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) was examined in competition with the cyclization process as shown in Scheme 7.^{7,39}

Scheme 5 Photolysis of 5'-(*tert*-butylketo)-derivatives of thymidine.

Scheme 6 Photolysis of 5'-(*tert*-butylketo)-derivatives of protected guanosine.

Similar experiments and results were reported for the 2'-deoxyinosin-5'-yl radical.⁴³

The isomeric ratio (5'*S*)/(5'*R*) substantially changes in all the above cases, depending on both the substrate structure and the experimental conditions. The effect of the solvent and the nature of the substituents at the O5' position play important roles in the stereoselectivity of the C5'-radical cyclization.^{35,41,42} The (5'*S*)/(5'*R*) ratio depends on the bulkiness of the C5'-OR substituent and the water solvation through intermolecular hydrogen bonding. The chair transition states of the pro-(5'*S*) and pro-(5'*R*) conformers, with the 5'-OH in the equatorial or the axial position, respectively, are illustrated by structures **42** and **43** (Figure 3). In aqueous solution, only the pro-(5'*R*) conformer may be stabilized by hydrogen bonding, involving either the N3 of the base (**43**) or the oxygen of the sugar ring (not shown). The (5'*R*)/(5'*S*) ratios obtained in water for 5',8-cyclo-2'-deoxyadenosine and 5',8-cyclo-2'-deoxyguanosine isomers were 6:1 and 8:1, respectively. In contrast, the (5'*S*) stereoselectivity of the cyclization reaction in

Scheme 6 is due to the steric hindrance between the guanine moiety and the 5'-*O*-*tert*-butyldimethylsilyl (TBDMS) substituent, which forces the 5'-*O*-TBDMS into the equatorial position. The (5'*R*)/(5'*S*) ratios of approximately 4 and 3 were reported for 5',8-cyclo-2'-deoxyadenosine and 5',8-cyclo-2'-deoxyguanosine lesions, respectively, in double-stranded DNA (dsDNA).^{14,44}

A study of (5'*S*)-5',8-cyclo-2'-deoxyadenosine (**23**, Figure 2) stability in aqueous medium revealed (i) that the glycosidic bond was >40-fold more resistant to acidic hydrolysis than that in 2'-deoxyadenosine and (ii) that no adenine was released, as evidenced by the intact C5'–C8 covalent bond.⁴⁵ Under sunlight irradiation, **23** photoisomerizes to the (5'*R*) isomer **24**, whereas the latter compound does not isomerize under the same conditions.⁴⁶ This one-way photoisomerization of **23** to **24** has been explained by invoking a heterolytic cleavage of the C–O bond to afford benzyl-type cations, which subsequently undergo nucleophilic trapping by water with concomitant isomerization. The isomer **24** is more easily

Scheme 7 Photolysis or one-electron reduction of 8-bromoadenosine.

Figure 3 Proposed transition state structures leading to 5'S (a) or 5'R (b) 5',8-cycloguanosines.

repaired when these cyclopurine lesions are formed in DNA (see below), and an extension of this study in single-stranded DNA (ssDNA) or dsDNA would be of value.

The C5' radicals of pyrimidine nucleosides may also cyclize to give the analogous diastereomeric mixtures of 5',6-cyclopyrimidines.^{47,48} Several of these derivatives have been incorporated in oligonucleotides and their properties investigated.^{48,49} However, there is no evidence of 5',6-cyclopyrimidine

formation *in vitro* or *in vivo* either in ssDNA or dsDNA. In this context, the rate constant of the cyclization of the substituted thymid-5'-yl radical was measured and found to be 2–3 orders of magnitude slower than the analogous substituted 2-deoxyguanosin-5'-yl radical (cf. Scheme 5).⁴⁷ Thus, the cyclization of C5' radicals in the pyrimidine series remains an important reaction for its synthetic applications in medicinal chemistry,⁵⁰ while the chemistry of C5' peroxyl radicals in oxidative DNA damage is better understood (see above).

2.3 Repair and Mutagenicity Studies on 5',8-Cyclopurine Lesions

Synthetic oligonucleotides containing (5'S)- and (5'R)-5',8-cyclo-2'-deoxyadenosine at selected sites were prepared by solid-phase synthesis in order to elucidate the biochemical features of such lesions.^{51,52} In 2000, (5'S)- and (5'R)-5',8-cyclo-2'-deoxyadenosine were reported

by two groups to be substrates of the NER pathway, but not of other repair pathways.^{51,52} Neither the (5'*S*)- nor the (5'*R*)-isomer is recognized by human DNA glycosylases active in the BER pathway. Furthermore, both isomers were found to be relatively poor substrates for the NER pathway, where the (5'*S*) isomer is repaired more efficiently than the (5'*R*) isomer. The (5'*S*) isomer was found to strongly block gene expression⁵² and to cause transcriptional mutagenesis.⁵³ It was also reported that stereospecific differences between the (5'*S*) and (5'*R*) isomer residues affect the relative resistance to exonucleolytic activity and give rise to different efficiencies of translesion synthesis by human polymerase η .⁵⁴ On the basis of these findings, both groups proposed that these lesions may be responsible for the neurodegeneration in patients suffering from xeroderma pigmentosum (XP) who lack the capacity to carry out NER.^{51,52} The clinical and neuropathological aspects of the XP disease were recently described, and the sound set of criteria presented indicate the 5',8-cyclopurine lesion as the most likely DNA lesion to play a role in this neurological disease.^{27,55} The 5',8-cyclopurine lesions have also been identified in mammalian cellular DNA *in vivo*, where their levels are enhanced by oxidative stress.^{27,28}

2.4 C5' Radicals in Ribonucleosides

The chemistry of 5',8-cyclopurine nucleosides was originally investigated in ionizing radiation studies, and these nucleosides were first observed as products in the reaction of HO $\cdot$ radicals with adenosine.^{15,16,28} One-electron reduction of 8-bromoadenosine in pulse radiolysis experiments has led to the site-specific generation of adenosin-5'-yl radical **44** (Scheme 8).⁵⁶ 8-Bromoadenosine captures electrons and rapidly loses a bromide ion to give the corresponding C8 radical, which intramolecularly abstracts a hydrogen atom (cf. **36** in Scheme 7 for the analogous 2'-deoxyadenosine). The reaction is partitioned between the C5' and C2' positions in a 60:40 ratio, leading to adenosin-5'-yl radical **44** and adenosin-2'-yl radical (see below). Radical **44** cyclizes intramolecularly to give the aromatic aminyl radical **45**. The reported rate constant of $1.0 \times 10^4 \text{ s}^{-1}$ is more than one order of magnitude slower than the analogous cyclization of

Scheme 8 Cyclization of the adenosin-5'-yl radical.

the 2'-deoxyadenosin-5'-yl radical, probably due to the conformational changes in going from *ribo* to 2'-deoxyribo derivatives. Product analysis of these reactions evidenced the formation of 5',8-cycloadenosine in a (5'*R*)/(5'*S*) diastereomeric ratio of 3.5:1. Similar experiments and results were reported for the inosin-5'-yl radical.⁴³

3 OXIDATION OF THE C4' POSITION

3.1 Generation of C4' Radicals

The C4' is probably the most well-studied position on the deoxyribose and it was the first position for which model studies were performed. Oxidation of C4' position has been observed in the presence of iron bleomycin,^{57–59} Cu(phen)₂,²² and enediyne antibiotics,⁸ as well as under conditions that generate reactive hydroxyl radicals.

3.2 Model Studies and Fate of the C4' Radical

Depending on experimental conditions, 4' oxidation chemistry can follow several pathways. For example, only 4'-hydrogen abstraction to give **46** has been observed with duplex DNA and iron bleomycin, and resulted mainly in two paths (Scheme 9).⁶⁰ Path A affords the C4'-oxidized abasic site **47** (or 2-deoxypentose-4-ulose lesion) and free base, whereas path B leads to a strand break and subsequent formation of 3'-phosphoglycolate (3'-PG) residue **48**, base propenal **49**, and 5'-phosphate terminus **15**.

The fate of the C4' radical, either in nucleosides or oligonucleotides, has been investigated in some

Scheme 9 Main degradation pathways for the C4' radical.

Figure 4 Photolabile precursors of the C4' radical.

detail under oxygen-free and aerobic conditions.³³ Oligonucleotides functionalized with a modified unit **50** or **51** (Figure 4), which promoted the selective generation of the C4' radical under photolytic conditions, were synthesized.

In the absence of added traps, the C4'-radical **46** in ss- or ds-oligonucleotides yields the oligonucleotide phosphates **15** and **12** as main products (Scheme 10). A heterolytic cleavage gives radical cation **53** and 5'-phosphate **15** with a rate constant of about 10^3 s^{-1} for an ss-oligonucleotide and about 10-fold slower for the corresponding reaction in a ds-oligonucleotide.³⁴ Spectroscopic evidence for the radical cation intermediate was obtained by electron spin resonance (ESR) and chemically induced dynamic nuclear polarization (CIDNP) techniques.^{61,62} This oxidizing radical cation is capable of oxidizing a neighboring guanine base.⁶³ The heterolytic cleavage is favored over a homolytic β -cleavage owing to the effective solvation of the ensuing ions.⁶⁴ Trapping of **53** by H_2O generates radical **54**, which undergoes a second heterolytic cleavage to give phosphate

12 and radical cation **55**. In the presence of GSH at millimolar levels, the heterolytic cleavage of radicals **46** and **54** competes with hydrogen abstraction from GSH (Scheme 10), and radical **46** abstracts hydrogen from a thiol with a rate constant of $1.9 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$.⁶⁵ The stereoselectivity of the H-trapping reaction is remarkable. Radical **46** in ss-oligonucleotides reacts nearly unselectively with GSH (**5:52** ≈ 1.5), while in ds-oligonucleotides the same species leads predominantly to the natural 2'-deoxyribonucleotides (**5:52** ≈ 9).³⁴

In the presence of O_2 , C4' radical **46** is trapped very rapidly ($2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) to give peroxy radical **57** (Scheme 11). However, this reaction was found to be reversible. The rate constant from ss-4'-DNA peroxy radical is 1.0 s^{-1} at ambient temperature.⁶⁵ As detected by ESR,⁶⁴ peroxy radicals abstract hydrogen from GSH with a rate constant of $\leq 400 \text{ M}^{-1} \text{ s}^{-1}$,⁶⁶ and the resulting hydroperoxide **58** has been isolated and characterized.^{65,67} Subsequently, the hydroperoxide **58** is converted to cation **59** (Criegee rearrangement), which, following β -elimination (**60**) and subsequent hydrolysis, leads to the oligomeric fragments 5'-phosphate **15** and 3'-PG **48** as well as base propenal **49**. Therefore, strand cleavage depends on the concentration of the hydrogen donor. At low GSH concentration, strand scission is the result of a spontaneous heterolytic cleavage that occurs even under aerobic conditions. It should be emphasized that the 5'-phosphate strand terminus (**15**) is formed under both aerobic and anaerobic conditions (cf. Schemes 10 and 11). However, at the 3' terminus, the 3'-PG fragment product **48** is characteristic of aerobic conditions, whereas the 3'-phosphate **12** is characteristically formed under anaerobic conditions.

According to the mechanism proposed by Stubbe *et al.*, the 2-deoxypentose-4-ulose lesion **47** is produced by oxidation of the C4' radical **46** to cation **61**, which is trapped by H_2O to give the cyclic hemiacetal **62**. Hydrolysis of **62** affords the observed lesion (Scheme 12).^{10,68} After H-abstraction from DNA, the bleomycin/ $\text{Fe}^{2+}/\text{O}_2$ complex was considered to effect the oxidation step to cation **61**. The subsequent partition ratio (between Path A and B in Scheme 9) depends on the concentration of O_2 . Model studies confirmed that the new oxygen atom at C4' does not come from oxygen but instead comes from the solvent, while

Scheme 10 Fate of the C4' radical under anaerobic or reducing conditions.

Scheme 11 Fate of the C4' radical under aerobic conditions.

metal oxides can easily induce the oxidation step⁶⁹ to cation **61** and corroborated the mechanism in Scheme 12.

The 2-deoxypentose-4-ulose residue **47** also exists in the hydrated form **63**, which is expected to be in equilibrium with the cyclic form **64** (Scheme 13). It is an abasic site, also called a 4'-keto abasic site and is abbreviated as **C4-AP**.

3.3 Biochemical Studies Involving the C4-AP Lesion

3.3.1 Incorporation of Caged C4-AP in Oligonucleotides

This C4'-oxidized abasic site is the result of a variety of DNA damaging agents, accounting for ~40%

Scheme 12 Proposed mechanism of 2-deoxypentos-4-ulose formation.

Scheme 14 Independent generation of C4-AP in model oligonucleotides.

Figure 5 A biochemical precursor of C4-AP.

of the lesions produced by the antitumor agent bleomycin. This lesion also exhibits unique biochemical and biological effects in DNA. Oligonucleotides containing the C4'-oxidized abasic site at a defined position along the sequence have been prepared and the effects of this lesion on DNA have been reported. Greenberg and coworkers reported the first general method for the synthesis of oligonucleotides containing this lesion.⁷⁰ Modified oligonucleotides **65**, incorporating nitroveratryl, a photosensitive protecting group, were prepared, and subsequent photolysis of the desired ss- or ds-oligonucleotides independently generated the C4'-oxidized abasic site **64** (Scheme 14). This concept has also been studied by others.⁷¹

An alternative general method for the preparation of the C4'-oxidized abasic site was also reported.⁷² Here, 4'-azido-2'-deoxyuridine-5'-triphosphate is incorporated into duplex DNA using a primer and HIV-1 reverse transcriptase. The two strands of the duplex are separated on the basis of size after cleavage with a restriction enzyme. After treatment with uracil-DNA glycosylase, an enzyme that hydrolyzes uracil from the 2'-deoxyribose anomeric position, the ssDNA containing 4'-azido-2'-deoxyuridine **66** (Figure 5) resulted in the quantitative release

of uracil and azide and the generation of ssDNA containing the C4'-oxidized abasic site. This lesion was characterized directly by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) and indirectly by subsequent reduction, enzymatic digestion, and gas chromatography-mass spectrometry (GC/MS). Synthetic methods for the preparation of gapped 3'-PG/5'-P lesions and the study of their structures by two-dimensional (2D) nuclear magnetic resonance (NMR) methods have also been reported.⁷³

The stability of the C4'-oxidized abasic site in both ss- and dsDNA has been determined. A half-life of 7.8 hours (37 °C, 100 mM NaCl at pH 7.5)⁷⁰ was found in ssDNA and 26 hours (37 °C, 100 mM NaCl at pH 7) in dsDNA.⁷² The rate constant in ssDNA is three times faster, suggesting that duplex DNA stabilizes the lesion, although pH conditions and the sequences were different in the two studies. A similar effect due to DNA structure has recently been reported for the 2-deoxyribonolactone lesion, whose half-life was found to be 20 hours in ssDNA and 32–54 hours in dsDNA. Thus, sugar lesion stability appears to be sensitive to both sequence and sequence context (ssDNA vs dsDNA).

3.3.2 Analytical Detection and Quantification of the C4-AP Lesion

A GC-MS approach was proposed for the quantification of 2-deoxypentos-4-ulose and 3'-PG pathways.⁷⁴ Another selective method for detecting femtomole amounts of the C4'-oxidized abasic site in DNA exploits the selective reactivity of the 1,4-dicarbonyl groups in the lesions with a biotinylated probe.⁷⁵ The adducts are quantified using a fluorescent assay.

Mass spectrometry was employed to detect the C4-AP from intrastrand or interstrand cross-links in cellular DNA,⁷⁶ as well as at specific positions in DNA fragments.⁷⁷ In particular, cyclic adducts were formed with deoxycytidine. DNA interstrand cross-links are deleterious to cells because they block replication and transcription.⁷⁸ By means of duplexes in which **64** is produced from a synthetic precursor, the lesion was shown to produce interstrand cross-links where both strands were intact, as well as cross-links where the strand containing C4-AP was cleaved.⁷⁹ The yields of these products depend upon the surrounding nucleotide sequence. When C4-AP lies opposite dA, cross-linking occurs exclusively with the adjacent dA on the 5'-side.^{80,81}

3.3.3 Repair of the C4-AP Lesion

The ability to generate the C4-AP or the 3'-PG/5'-P lesions in any sequence context could elucidate the lesion structure (in both ss- and dsDNA lesions). The efficiency of *in vitro* C4-AP repair by the Ape1 protein (the major human abasic site endonuclease) and β -polymerase has been studied.⁸² Ape1 catalyzed effective incision at C4-AP at a rate that may be only a few times less than that for the incision of hydrolytic native abasic (AP) sites at the same location. Ape1 hydrolyzed 3'-PGs 25 times more slowly than the abasic site. The repair of C4-AP has also been studied with a variety of DNA polymerases *in vitro*.⁸³

3.4 C4' Radicals in Ribonucleotides

The site-specific generation of C4' radical in ribonucleosides and RNA has received much less attention than its DNA counterpart, and it should be noted that iron bleomycin cleaves RNA much less efficiently than DNA.⁸⁴ An oligonucleotide containing the modified methyl ketone **67** as photolytic precursor of the C4' radical (Scheme 15) has been synthesized.⁸⁵ In the presence of GSH and in competition with hydrogen abstraction from GSH to give **69**, the

Scheme 15 Generation of C4' radical in ribonucleotides.

4'-RNA radical **68** cleaves heterolytically to give the radical cation **70** and phosphate **15**. Assuming a $k_H = 1 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ for the reaction of radical **68** with GSH, a rate constant of $k_f = 5 \times 10^2 \text{ s}^{-1}$ is calculated for the heterolytic cleavage of **68**. The cleavage rate of the corresponding 4'-DNA radical is more than three times faster. A destabilizing effect of the additional 2'-OH group⁸⁶ is considered to be responsible for the lower cleavage rate of the ribonucleotide radical.

Under aerobic conditions, the expected products **15** and **48** were produced (Scheme 15).³³ However, their ratio changes substantially, since the value of **48/15** goes from 0.33 for the 4'-DNA radical to 3.0 for the 4'-RNA radical **68**. This effect was attributed to the retardation of β -elimination after the Criegee rearrangement (cf. Scheme 11).

4 OXIDATION OF THE C3' POSITION

4.1 Generation and Model Studies

Metallointercalators generally bind to the minor groove of dsDNA and abstract mainly C1', C4', and C5' H atoms from the sugar backbone. However, phenanthrenequinone diimine complexes of rhodium(III) intercalate in the major groove of dsDNA and have been postulated to abstract C3' H atoms from deoxyribose upon photoactivation,⁸⁷ although evidence suggests that H2' may be abstracted during photocleavage.⁸⁸ Under aerobic conditions, the C3' chemistry of **71** has thus been linked to the generation of 3'-phosphoglycolaldehyde (3'-PGA) **72**, base propenoate **73**, free base, as well as the oligonucleotide 3'-phosphate and 5'-phosphate termini at the site of strand scission (Scheme 16).

Site-specific radical-generating systems have been examined in some detail. The synthesis of *tert*-butyl ketone **74** or **75** and the conditions

Scheme 17 Independent generation of C3' radical in model studies.

in which Norrish-type I photocleavage gave the desired C3' radical **76** were the subject of initial work.⁸⁹ In the presence of Bu_3SnH as a hydrogen donor, both derivatives gave **77**, a 1:1 mixture of isomers (Scheme 17).

The *tert*-butyl ketone **75** (or its analogous acetyl derivative) has been incorporated into oligonucleotides and used as a photoactivated precursor of C3' radicals in ssDNA.^{90,91} While some products have been successfully identified, the mechanism of their formation is far from being understood. The thymidin-3'-yl radical abstracts hydrogen from GSH to give the reduced product in an undetermined β : α anomeric ratio.⁹⁰ Under aerobic conditions, the same radical was found to produce the labile 3'-ketodeoxynucleotide **79**, which led to **80** and free base, as well as the 5'- and 3'-phosphate-terminated oligomers (**15** and **12**) (Scheme 18).⁹¹ The expected 3'-PGA was accompanied by 3'-PG as well as 5'-aldehyde-terminated oligonucleotides. The formation of these fragments has been rationalized by oxidation of the C4' radicals of the same nucleotide and by oxidation of the C5' radicals of the 3'-adjacent nucleotide. The authors suggested the radical translocations from **82**, shown in Scheme 19, with formation of radicals **83** and **84**,

Scheme 16 Fate of the C3' radical in DNA.

Scheme 18 Fate of the C3' radical under aerobic conditions.

Scheme 19 Postulated radical translocation from C3' to C4' and C5' positions.

respectively. It should be noted that these findings are based on ss-oligonucleotide experiments. The mechanism of the transformation of peroxy radical **78** to 3'-ketodeoxynucleotide **79** has not yet been elucidated. The fate of this peroxy radical may be similar to that observed in the oxidation of C1' radicals: that is, release of O₂^{•−} from the peroxy radical, trapping of the corresponding cation by water, and β-elimination of the phosphate. Since the electronic environments of the C1' and C3' cations differ, the O₂^{•−} release in radical **78** should be much slower, rendering the intramolecular processes depicted in Scheme 19 plausible.

The mechanism of 3'-PGA (**72**) formation has not been clarified. It was suggested that, following hydroperoxide formation, a molecular rearrangement occurs with insertion of an oxygen atom into the deoxyribose ring, which further decomposes to

form 3'-PGA together with other products.⁸⁷ C3' radical degradation may not be the only pathway leading to 3'-PGA, and a method for the quantification of 3'-PGA residues has also been reported. After DNA irradiation and enzymatic digestion, the aldehyde moiety in 3'-PGA is derivatized to a stable oxime with pentafluorobenzylhydroxylamine, followed by extraction and characterization by GS/negative chemical ionization/MS.^{92,93} A stable isotopically labeled [¹³C₂]PGA was synthesized and used as an internal standard. In the presence of DNA, the detection limit was 30 fmol per sample, corresponding to two molecules of PGA in 10⁶ nucleotides for 170 μg of DNA. The application of this method for quantifying 3'-PGA residues revealed different yields for γ and α radiations.⁹²

Scheme 20 2'-Deoxygenation by ribonucleotide reductases.

Scheme 21 Independent generation and fate of C3' radical in ribonucleosides.

4.2 C3' Radicals in Ribonucleotides

The ribonucleotide reductase enzymes catalyze the conversion of 5'-(di or tri)-phosphate esters of ribonucleosides **85** to 2'-deoxynucleotides **86** in all organisms (Scheme 20). A radical-based mechanism for their action, derived from the results of several biological studies, has been established.^{94,95} The key steps involve formation of C-3' radical via hydrogen atom abstraction by a cofactor-induced thiyl radical and elimination of water prior to return of a hydrogen atom.

Biomimetic simulations of the free radical-initiated cascade reactions, postulated to occur at

the active site of ribonucleoside reductases, have also been performed.^{96,97} Synthesis of selenol ester **87** and subsequent photolysis (Scheme 21)⁹⁶ led to the site-specific generation of adenosin-3'-yl radical, and, with competition kinetic methods, it could be demonstrated that this radical effects the rapid elimination of the 2'-hydroxy group, leading to **91**, a reaction subjected to general base catalysis. The rate coefficient was determined as $1.5 \times 10^6 \text{ s}^{-1}$ by competition kinetics in the presence of 1 M triethylammonium acetate buffer at pH 7, and the elimination rate is about 10^3 times slower in the absence of the catalyst. A similar mechanism may also be feasible for the key steps of the enzyme-catalyzed reaction. A radical similar to **90** was also observed by pulsed electron paramagnetic resonance (EPR) and electron nuclear double resonance (ENDOR) spectroscopy in the deoxygenation of cytidine diphosphate by a mutant *Escherichia coli* ribonucleotide reductase.⁹⁸

5 OXIDATION OF THE C2' POSITION

5.1 Generation and Model Studies

Oxidation of the C2' is less common owing to the relatively higher C–H bond strength in DNA. Nevertheless, C2' oxidation in DNA has been observed under conditions that generate reactive hydroxyl radicals²¹ as well as in the photoirradiation of 5-halopyrimidine containing DNA.^{99,100} It is also expected that the C2' position in RNA would exhibit the same reactivity with the other positions of the deoxyribose. The photoreaction of 2'- α -iodo-2'-deoxyuridine (**92**) as a site-specific radical-generating system has also been explored. The reaction leads to a plethora of products that involve the formation of C2' radical **93** and C2' cation **96** (Scheme 22).¹⁰¹ Photoinduced

Scheme 22 Generation of C2' radical from 2'- α -iodo-2'-deoxyuridine.

homolytic cleavage of the C–I bond is followed by single-electron transfer in the cage before the diffusion of some reactive species. Under anaerobic conditions, the solvolysis product **97** as an anomeric mixture prevails with other proton elimination or cation translocation products to give **98** and **99**, respectively. In the presence of oxygen, the conversion of the C2' radical to the corresponding peroxy radical **94** is a consistent path that ultimately leads to the formation of erythrose **95** and uracil as well as to the C2'-hydroxylated product **97**.

The photoirradiation of **101** in a ds-oligonucleotide produced **102** (11%) and **100** (5.6%) under aerobic conditions, while the yield of **102** decreased with the yield increase of **100** in the absence of oxygen (Scheme 23).¹⁰¹ The photochemical dehalogenation of 5-halouracil-containing

DNA, where the hydrogen abstraction from the resulting uracil-5-yl radicals is atom-specific and highly dependent on the DNA structure, has been studied in detail.⁹⁹ Competitive C1' and C2' hydrogen abstraction was observed from the 2-deoxyribose at the 5' side in B-form DNA, affording the oligonucleotides **102** and **100**.^{101,102} In analogous experiments with Z-form DNA, product **100** is significantly suppressed and the formation of **102** is accompanied by C2' α -hydroxylation.¹⁰³

Therefore, the formation of D-erythrose abasic site (C2-AP, **102**) and the hydroxylation at C2' position are considered to be the key C2' oxidation products. Early studies on the γ irradiation of DNA also included a report of the formation of erythrose-containing sites.¹⁰⁴ The formation of **102** from the C2'-OO• radicals has been explained by

Scheme 23 Generation of C2' radicals in oligonucleotides.

several mechanistic pathways, although a definitive confirmation is not yet available.^{102,103}

5.2 Biochemical Studies with C2-AP

In addition to the 5-halouracil photochemical system described above for the synthesis of oligonucleotides containing an erythrose abasic site (C2-AP), the selective *in situ* generation of the lesion at a defined oligonucleotide site has been described.¹⁰⁵ A phosphoramidite derivative of a protected ribitol was prepared, which, following oligonucleotide incorporation and deprotection, afforded **103**. Periodate oxidation of the vicinal diol affords C2-AP (**102**), as shown in Scheme 24. Although incorporation of the precursor into oligonucleotides has only 50% efficiency, *in situ* conversion of the precursor to C2-AP was nearly quantitative.

This lesion is rapidly cleaved by piperidine at 90 °C.¹⁰⁵ Heating of this abasic site under alkaline conditions causes a retroaldol reaction, resulting in a strand break with subsequent formation of oligonucleotides 3'-PGA **72** and 5'-phosphoglycolaldehyde

Scheme 24 Independent generation of the C2-AP lesion in oligonucleotides.

104 (Scheme 24).^{102,106} However, cleavage by 0.1 M NaOH at 37 °C reveals that the erythrose abasic site is considerably less labile to hydrolysis (half-life of 3.3 h) than other abasic lesions.¹⁰⁵ The 3'-residue (**72**) is chemically identical, but mechanistically unrelated, to the 3'-PGA residue product of the C3' radical oxidation (see above).

The results of two *in vitro* studies suggest possible biological consequences for the erythrose abasic lesion.^{106,107} Like other abasic lesions, deoxyadenosine is preferentially incorporated opposite to the abasic site, but is a strong inhibitor to polymerase extension. This lesion is incised by phosphodiesterases but is not a substrate for endonuclease III, even though a Schiff base is formed. Ape1 (see Section 3.4) incises C2-AP, but the 5'-phosphorylated fragment is not a substrate for the lyase activity of DNA polymerase β .¹⁰⁸ Excision of the lesion is achieved by strand displacement synthesis in the presence of flap endonuclease during which C2-AP and the 3'-adjacent nucleotide are replaced. C2-AP is also a substrate for the bacterial UvrABC NER system.¹⁰⁸

5.3 C2' Radicals in Ribonucleosides

Compound **105** was synthesized as a site-specific adenosin-2'-yl radical-generating system upon photolysis. The radical **106** was generated and was trapped by GSH (Scheme 25),⁵⁶ leading to the ribo and arabino products **107** and **108**, respectively, in a 1:3.5 ratio. The preferred attack of the thiol from the α -face of the C2' radical is due to the efficient β -face shielding by the adenine moiety. Adenine was also a reaction product. The ratio $k_H/k_f = 4.3 \text{ M}^{-1}$ was determined by competition kinetics and indicates a relatively rapid β -elimination.

The same adenosin-2'-yl radical was obtained by one-electron reduction of 8-bromoadenosine (see above) in pulse radiolysis experiments (Scheme 26).⁵⁶ A k_f value of $1.1 \times 10^5 \text{ s}^{-1}$ is obtained by measuring the oxidizing radical formed upon adenine release. Heterolysis of the glycosidic bond in radical **109** was suggested to produce both the radical cation **110** and the adenine. Similar experiments and results were reported for inosin-2'-yl radical, which also gives **110** and hypoxanthine (Hy) upon heterolysis of the glycosidic bond.⁴³

Scheme 25 Independent generation of C3' in ribonucleosides.

Scheme 26 Postulated heterolysis of the glycosidic bond of C2' radical.

6 OXIDATION OF THE C1' POSITION

6.1 Generation and Fate of the C1' Radical

The 2-deoxyribonolactone lesion (or C1'-oxidized abasic site) is the outcome of the oxidation of the C1' position of DNA nucleotides and has been implicated in DNA strand scission, mutagenesis, and covalent cross-linking to DNA-binding proteins.^{3,4,8–10} The deoxyribonolactone lesion is known to be the result of a variety of toxic agents, including enediyne antibiotics (e.g., NCS-Chrom), bis(phenanthroline) copper, cationic manganese porphyrins, oxoruthenium complexes, ultraviolet irradiation, and ionizing irradiation.^{8–10,12,15,16} The chemical mechanisms for oxidized abasic site generation by these agents have been the subject of intensive investigation, and, while the details vary among damage reagents and conditions, key features of the damage process include hydrogen abstraction at the C1' position, nucleotide oxygenation,

and extrusion of the nucleobase to produce the 2-deoxyribonolactone (L) lesion in duplex DNA.

6.2 Model Studies for the Independent Generation of C1' Radicals

Significant efforts have been devoted to creating a site-specific radical-generating system and to incorporating the L lesion in duplex DNA. The specific generation of the C1' radical has been achieved by two independent synthetic routes involving the photoinduced cleavage of the corresponding *tert*-butyl ketone **111** (Scheme 27).^{109,110} The 2'-deoxyuridin-1'-yl radical, generated by photolysis of *tert*-butyl ketone **111** or **112** in water, was studied spectroscopically by EPR and laser flash photolysis (LFP) methods.^{110,111} Density functional theory (DFT) calculations at the UB3LYP/6-311G** level have also revealed structural properties of this radical, and hyperfine coupling (hfs) constants determined by EPR as well as optical transitions observed in the ultraviolet–visible (UV–vis) region of the LFP spectrum have been defined.^{110,111} The radical center is not planar, and the energy profile for the interconversion of the two anomeric forms **113** and **114** (Scheme 27) was determined computationally. A broad band in the 290–370 nm region with $\lambda_{\text{max}} = 320$ nm is characteristic of the 2'-deoxyuridin-1'-yl radical. The vertical optical transitions [spin] singly occupied molecular orbital (SOMO) $\rightarrow \pi^*(\text{uracil})[\alpha]$ and $\pi(\text{uracil}) \rightarrow \text{SOMO}[\beta]$ were computed at

Scheme 27 Independent generation of C1' radicals.

296 nm (oscillator strength $f = 0.010$) and 378 nm ($f = 0.06$), respectively.¹¹¹

The 2'-deoxyuridin-1'-yl radical abstracts hydrogen from β -mercaptoethanol, cysteine, and GSH with rate constants of and 2.3×10^6 , 2.9×10^6 , and $4.4 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$, respectively, to give a β : α anomeric ratio in the 1.3–2.0 range.¹¹¹ Since the β : α ratio was insensitive to the initial concentration of thiol and the precursor, it was suggested that the C-1' radical rapidly inverts (Scheme 27), and that the β / α distribution depends on the degree of the shielding effect of the two γ substituents in the sugar ring: that is, OH versus CH_2OH . The *tert*-butyl ketone **111** has been incorporated into oligonucleotide sequences, and the reactivity of the C1'-nucleotide radical toward thiols has been addressed.¹¹² Using β -mercaptoethanol, β : α ratios of 4.2 and 6.5 were determined for radical **115** (B = uracil) trapping in ss- and ds-oligonucleotides, respectively (Scheme 28). This increase in stereoselectivity favors the restoration of the naturally occurring β -deoxynucleotide. Those α -deoxynucleotides produced during γ radiolysis of DNA under anaerobic conditions have been shown *in vitro* to be premutagenic.^{113,114} The C1' radical **115** has been suggested to abstract a hydrogen atom from a thiol to give a mixture of β -anomer **116** and α -anomer **117** (Scheme 28).

In the presence of O_2 , radical **115** leads to abasic site damage with the formation of the 2-deoxyribonolactone residue (**100**).^{4,9,12,115} The reaction of selectively generated 2'-deoxy-uridin-1'-yl

Scheme 28 Fate of the C1' radical under reducing and oxidative conditions.

radical with molecular oxygen gives the corresponding peroxyl radical with a rate constant of $1 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ (cf. structure **118** in Scheme 28).¹¹¹ The fate of this peroxyl radical has been investigated in some detail by ^{18}O labeling and LFP experiments.^{116,117} The labeling experiments demonstrated the partition between two channels, where the ribonolactone carbonyl oxygen is derived from molecular oxygen and a water molecule.¹¹⁷ In the LFP experiment, the rapid release of $\text{O}_2^{\cdot-}$ from the peroxyl radical corresponds to a rate constant of $1.5 \times 10^4 \text{ s}^{-1}$.¹¹⁷ Similar reactions in dsDNA have been previously reported.¹¹²

Under physiological conditions, oxygen and GSH trapping of C1' radicals are competitive processes, because of the low O_2 concentration in the nucleus. Since the rate constant for reaction of the DNA peroxyl radicals with GSH is $\leq 400 \text{ M}^{-1} \text{ s}^{-1}$,⁶⁶ superoxide release from C1' nucleotide peroxyl radicals is orders of magnitude faster than peroxyl trapping at physiological GSH concentrations ($\sim 5 \text{ mM}$). Once formed, the C1' peroxyl radicals **118** expel superoxide radical anion to give C1' cations **119**, affording

100 much faster than the respective trapping by GSH to give hydroperoxides.¹¹⁸

In the presence of metal complexes, the strongly reducing C1' radical **115** undergoes oxidation to the corresponding cation **119** (Scheme 28).^{11,12} Rate constants for the reaction of the 2'-deoxyuridin-1'-yl radical **113** with CuCl₂ and FeCl₃ are reported as 7.9×10^7 and $1 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, respectively.¹¹¹

Therefore, 2-deoxyribonolactone (**L**) has been identified as the only C1' oxidation product. Radical translocation from the base unit to C1' position has been suggested in many radical-based DNA studies as the route to **L** formation. For example, the photochemical dehalogenation of 5-halouracil-containing DNA (see also oxidation of the C2' position) has been investigated in detail.⁹⁹ Hydrogen abstraction from the resulting uracil-5-yl radicals is atom-specific and highly dependent on the DNA structure, suggesting that this approach could also be applied as a probe for the DNA conformations in living cells.

6.3 Independent Generation of the 2-Deoxyribonolactone Lesion in Oligonucleotides

2-Deoxyribonolactone (**L**) is an alkali-labile lesion and, under alkaline conditions, results in strand scission (Scheme 29) with formation of 3'-phosphate **15** and 5'-phosphate **12** termini. Thus, **L** cannot be incorporated into chemically synthesized deprotected oligonucleotides under basic conditions.

Scheme 29 Products of alkali treatment of the **L** lesion.

Scheme 30 Radical [1,5]-translocation to the C1' position.

In addition to the photolysis of the corresponding oligonucleotides containing the *tert*-butyl ketone **111**,^{112,118} a general method has been developed for the *in situ* generation of the lesion at a defined site of oligonucleotides using known radical translocation approaches.^{119–121} Efficient 1,5-radical translocation protocols for the selective generation of C1' radicals **123** (Scheme 30) and their subsequent trapping in nucleosides have been proposed.^{119,120} In particular, a synthesis has been reported,^{122,123} which is based on the photochemical conversion of the nitroindole nucleoside **124** (selectively incorporated in an oligonucleotide) to **100** with simultaneous expulsion of nitrosoindole **125** (Scheme 31). The single **L**-containing strands were hybridized with the complementary strand for biophysical and biochemical studies. NMR structural studies have illuminated aspects of the conformation of the DNA containing this lesion.¹²⁴ The procedure was also extended to double-strand synthesis by irradiation of the duplex in which one strand contains the nitroindole residue.¹²⁵

An alternative photochemical approach for the introduction of **L** in ds-oligonucleotides has also been developed,^{126,127} where a C1' nitroveratryl cyanohydrin phosphoramidite analog (**126**, Scheme 32) was synthesized and used for the preparation of ss-oligonucleotides. Irradiation at 350 nm quantitatively converted **126** to the 2-deoxyribonolactone lesion.

6.4 Biochemical Studies

The degradation of **L**-containing DNA was investigated in some detail.^{125,126} The cleavage through α,β - and γ,δ -elimination at the site of the lesion has been established with identification of the reaction products (Scheme 29). The degradation kinetics was investigated as a function of pH, temperature, length, and ionic strength.¹²⁵ Incubation of **L**-containing DNA under simulated

Scheme 31 Independent L-lesion formation under photochemical conditions.

Scheme 32 Photochemical (nonradical) generation of L lesion.

physiological conditions led to DNA fragmentation after two consecutive elimination reactions. DNA cleavage occurred with a half-life of ~ 20 hours in ssDNA and of 32–54 hours in duplex DNA, depending on the identity of the deoxynucleotide paired opposite to the lesion site ($A > C > G > T$).¹²⁷ The initial α,β -elimination reaction was the rate-determining step for the formation of methylene furanone and phosphorylated DNA products.

In the case of the minor groove-binding copper phenanthroline ($\text{Cu}(\text{phen})_2$) conjugate, the formation of 5-methylene furanone (**121**) and 3'- and 5'-terminus phosphates occurs without alkali-labile conditions in a much faster kinetic regime than expected (cf. Scheme 29).¹¹⁸ An L-containing ds-oligonucleotide resulted from photolysis of the corresponding oligonucleotide containing the *tert*-butyl ketone **111** (Scheme 27).^{112,118} $\text{Cu}(\text{OP})_2$ was shown to produce direct strand scission by effecting α,β -elimination from **100** (Scheme 29).¹²⁸

The approaches for the synthesis of L-containing DNA lesions described above have led to a better understanding of the toxicity, mutagenesis, and biochemical fate of the L lesion. This lesion is incised by AP endonucleases, suggesting a BER pathway for L removal.¹²⁹ The L lesion was also found to induce DNA polymerase-mediated mutagenesis¹³⁰ and transcriptional inhibition.¹³¹ These lesions form covalent adducts with DNA repair

proteins that metabolize AP sites, implying potential toxicity mechanisms,^{132,133} and long-patch base excision DNA L lesion repair prevents the formation of DNA–protein cross-links with DNA pol β .¹³⁴ The L lesion has been shown to have mutagenic properties unlike those of native abasic sites,^{135,136} although caution is needed for the interpretation of the experiments.⁴ The development of analytical methods for quantifying 2-deoxyribose oxidation products in isolated DNA and cells has been reported.^{137,138}

7 CONCLUSIONS

Oxidation of the sugar moiety in DNA is biologically relevant since, in most cases, it leads to an unstable or altered biomolecule that puts the repair machinery of the cell to test. DNA damage involving the 2-deoxyribose is caused by ROS and chemical mutagens. The ensuing DNA lesions involve either ss breaks repaired by NER enzymes, or deleterious ds breaks resulting from tandem and clustered DNA lesions and leading eventually to cell apoptosis or cell death.

The study of sugar DNA damage was initiated by studies on the effects of ionizing radiation involving mainly diffusible ROS and has progressed to the study of chemical nucleases and metal complexes which, through DNA binding, induce sequence-specific and position-specific damage.

Research in the area has been aided by model systems capable of photochemical-independent generation of a nucleosidyl or nucleotidyl radical in monomeric state or inserted in ss or dsDNA. Finally, these studies have more recently been extended to photosensitive precursors of specific damage products inserted in oligonucleotides. Independent generation of these lesions in DNA has allowed biochemical studies of their stability and mutagenic potential within the frame of the double helix as well as the elucidation of other biologically important events involving modification of nearby nucleobases and the formation of DNA–DNA and DNA–protein cross-links.

The small molecule and DNA fragments that arise from an initial H-atom abstraction from one sp^3 -hybridized C–H sugar bond are listed in Table 1 and have been described above, together with the assignment of the position of initial attack. As previously mentioned, there are still open questions, especially involving the less studied positions, which will continue to draw the attention of researchers in the field and the study of which will hopefully bring a thorough understanding of the biological significance of oxidatively formed sugar radicals in nucleic acids.

Reactions of Small Reactive Species with DNA

Nicholas E. Geacintov and Vladimir Shafirovich

Chemistry Department, New York University, New York, NY, USA

1 INTRODUCTION

The major source of endogenous reactive oxygen species (ROS) is aerobic metabolism,¹ while both ROS and reactive nitrogen species (RNS) and oxidizing halogen derivatives are secreted by macrophages and neutrophils, respectively, that arise at sites of inflammation.² These intermediates include small molecular reactive species such as hydrogen peroxide (H_2O_2), peroxynitrite (ONOO^-), hydrochlorous acid, and HOCl , as well as free radicals such as superoxide radical anion ($\text{O}_2^{\bullet-}$), nitric oxide ('NO), the hydroxyl radical ('OH), and the carbonate radical anion ($\text{CO}_3^{\bullet-}$).^{1–6} Molecular reactive species have even pairs of electrons, while free radicals have one unpaired electron, and therefore an odd number of electrons. Because of the presence of unpaired electrons, free radicals are typically more reactive than molecules with even numbers of electrons. In normal tissues, ROS/RNS are present at low concentrations and play a role in regulating the activation of transcription factors, cell proliferation, and apoptosis.^{7,8} Reactive oxygen and nitrogen species play a critical role in eliminating viral and microbial infections and thus function as an efficient cellular defense mechanism. However, under conditions of acute or chronic inflammation developed in response to a variety of pathogens, environmental pollutants, tobacco smoke, and other exogenous factors, the damage inflicted by this intrinsic physiological defensive mechanism becomes harmful to

biological macromolecules and tissues.^{9–11} Thus, the overproduction of ROS/RNS during the inflammatory response has been linked with the etiology of various diseases¹ and the inflammatory response.^{2,3}

In normal and healthy tissues, the potentially harmful impact of ROS/RNS is mitigated by detoxification reactions catalyzed by catalase and superoxide dismutase (SOD) as well as by nonenzymatic mechanisms that involve glutathione and other antioxidants.¹ The overexpression of ROS/RNS results in the development of oxidative stress, which is accompanied by a series of signaling events that trigger the generation of cytokines and chemokines. Furthermore, chemical reactions of ROS/RNS with cellular DNA generate lesions, which, if not repaired by cellular DNA repair mechanisms, can induce mutations and genomic instability. Chronic inflammation can also stimulate cell-proliferating growth factors that enhance the frequencies of mutations that foster the progressive transformation of cells to the malignant state.^{9,10,12}

2 REACTIVE SPECIES IN CELLULAR ENVIRONMENTS

2.1 Molecular Pathways of ROS/RNS Generation

The pathways that generate the spectrum of ROS and RNS during the inflammatory response are

Figure 1 Molecular pathways of generation of molecular (blue) and free-radical (red) species in living systems.

shown in Figure 1.^{2,3,5} The upregulation of inducible nitric oxide synthase (iNOS) in macrophages plays one of the key roles in the inflammatory response. This enzyme catalyzes the oxidation of arginine to citrulline to form nitric oxide, a unique intracellular messenger that modulates blood flow, thrombosis, and neural activity.¹³ The physiological concentrations of $\cdot\text{NO}$ are at a level of ~ 10 nM, which is sufficient to activate guanyl cyclase, but can rise to levels of ~ 1 μM in highly inflamed tissues.⁵ The level of $\cdot\text{NO}$ is regulated by the extremely rapid conversion of $\cdot\text{NO}$ to nitrate by oxyhemoglobin in red cells, which prevents the direct oxidation of $\cdot\text{NO}$ by O_2 and the formation of potentially toxic intermediates such as $\cdot\text{NO}_2$, N_2O_3 , and N_2O_4 .^{14,15}

In 1990, Beckman and coworkers showed that $\cdot\text{NO}$ is highly toxic even at very low concentrations if superoxide radical anions are simultaneously produced and react with $\cdot\text{NO}$ to form the powerful oxidant peroxynitrite, ONOO^- .¹⁶

This reaction is extremely rapid and occurs with a close to diffusion-controlled rate constant of $6.7 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$.¹⁷ *In vivo*, the concentration of the $\text{O}_2^{\cdot-}$ radical is tightly regulated (basal level of 0.1 nM) by SOD. The latter exists as distinct isoforms located in the mitochondria, cytoplasm,

and extracellular compartments of cells.⁵ The SOD enzymes catalytically convert $\text{O}_2^{\cdot-}$ radicals to oxygen and hydrogen peroxide:

The reaction of SOD and $\text{O}_2^{\cdot-}$ is very rapid and occurs with the rate constants of $\sim 2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ for both half-reactions of the catalytic cycle at 25°C over the pH range 5.0–9.5.^{18,19} Thus, $\cdot\text{NO}$ is a unique species produced in cells in sufficiently high concentrations to compete with SOD for $\text{O}_2^{\cdot-}$.⁵ In inflamed tissues, superoxide is overproduced as a result of the upregulation of NADPH oxidase and xanthine oxidase, electron leaks from mitochondria, and the uncoupling of the nitric oxide synthases leading to production of $\text{O}_2^{\cdot-}$ instead of $\cdot\text{NO}$.^{1,5} The H_2O_2 , derived from the dismutation of $\text{O}_2^{\cdot-}$ radicals, is regulated by catalase and peroxidase to levels of ~ 10 nM.²⁰ Neutrophils release large quantities of myeloperoxidase (MPO) which catalyzes the oxidation of halogen anions (Cl^- , Br^-) by hydrogen peroxide, thereby forming the highly reactive hypohalous acids (HOCl , HOBr).⁵ MPO also rapidly reacts with peroxynitrite to produce $\cdot\text{NO}_2$ radicals.^{21,22} *In vivo* $\cdot\text{NO}_2$ radicals rapidly react with an excess $\cdot\text{NO}$ to form N_2O_3 ,²³ a powerful nitrosating agent generated by macrophages.²⁴ Free radicals

generated at sites of inflammation initiate efficient lipid peroxidation associated with the formation of secondary radicals such as peroxy (ROO[•]) and hydroperoxy (HO₂[•]), as well as DNA-damaging reactive unsaturated aldehydes and epoxides.^{25,26}

2.2 General Aspects of ROS/RNS Reactivity

2.2.1 Molecular Reactive Species

In living systems, the inflammatory response is associated with the generation of a wide spectrum of molecular reactive species.^{1–3} Here we focus on small molecular reactive species such as ONOO[−], H₂O₂, and HOCl (Figure 1), which are present *in vivo* in extremely low concentrations under conditions of normal metabolism, and are overproduced at sites of inflammation. These molecular reactive species are strong oxidizing agents with two-electron reduction potentials^{27,28} in the range 1.08–1.37 V versus normal hydrogen electrode (NHE) (Table 1) and can potentially damage a wide spectrum of biomolecules. The oxidative processes initiated by molecular reactive species occur by two principal pathways: (i) two-electron oxidation without intermediate formation of free radicals and (ii) one-electron oxidation by highly reactive free radicals derived from the decomposition or the one-electron reduction of parent molecular reactive species.^{5,20}

Peroxynitrite (ONOO[−])

In neutral solutions, peroxynitrite exists in equilibrium with unstable peroxynitrous acid ONOOH (pK_a = 6.6), which spontaneously decomposes with the rate constant of 1.25 s^{−1} (25 °C).²⁹

Table 1 Two-electron reduction potentials (*E*₇ vs NHE) of molecular reactive species at pH 7.

Reaction	<i>E</i> ₇ (V)	Reference
H ₂ O ₂ + 2H ⁺ + 2e [−] ⇌ 2H ₂ O	1.32	27
HOCl + 2H ⁺ + 2e [−] ⇌ H ₂ O + HCl	1.08	27
ONOOH + 2H ⁺ + 2e [−] ⇌ HNO ₂ + H ₂ O	1.37	28

The decomposition products are nitrate anions, nitrogen dioxide, and hydroxyl radicals formed with a yield of $x \sim 0.28$.³⁰ In neutral solutions, the lifetime of peroxynitrite ($\tau_e = 1/k_a$), estimated from the equation $k_a = k_1[\text{H}^+]/(\text{H}^+ + K_a)$, is about 4 s at pH 7 (24 °C).³¹ However, *in vivo*, the formation of [•]OH radicals plays only a minor role because of the rapid reaction of ONOO[−] with CO₂, which is ubiquitous in tissues due to the high levels of bicarbonate (10–30 mM) in biological fluids.³² This reaction occurs with a rate constant of $2.9 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ (24 °C)³¹ and results in the formation of a highly unstable nitrosoperoxycarbonate (ONOOCO₂[−]) species, which rapidly decomposes (<100 ns) to form carbonate radical anions, CO₃^{•−}, and [•]NO₂ radicals with a yield of $y \sim 0.33$.³³

In aqueous solutions, carbon dioxide coexists in equilibrium with bicarbonate anions and its concentration can be estimated using the equilibrium constant of $1.1 \times 10^{-6} \text{ M}^{-1}$ for the reaction $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$.³⁴ In neutral solutions (pH 7) containing 25 mM NaHCO₃, the lifetime of peroxynitrite is reduced to ~20 ms as a result of (4).³¹

The toxic effects of peroxynitrite are most likely associated with free radicals derived from its decomposition.⁵ The classic example is the oxidation/nitration of tyrosine (1) (Figure 2).^{35,36} In this case, the lifetime of peroxynitrite calculated from the decay of its characteristic absorbance ($\lambda_{\text{max}} = 302 \text{ nm}$, $\epsilon = 1670 \text{ M}^{-1} \text{ cm}^{-1}$),³⁷ either in the absence of CO₂/HCO₃[−] or in the presence of 25 mM NaHCO₃ (pH 7.5), is independent on the tyrosine concentration. This observation is a clear indication that mechanisms that invoke a direct electrophilic attack by peroxynitrite or nitrosoperoxycarbonate on the tyrosine aromatic ring are inconsistent with the reaction kinetics. In turn, the yields of the major end products derived from the combination of tyrosyl radicals (2) with [•]NO₂ radicals to form 3-nitrotyrosine (3), and the recombination of tyrosyl radicals (2) to form 3,3'-dityrosine (4), are in complete agreement with the free-radical mechanisms summarized in Figure 2.^{35,36}

A two-electron oxidation mechanism without the intermediate formation of free radicals

Figure 2 Free-radical mechanism of oxidation/nitration of tyrosine by peroxynitrite and nitrosoperoxycarbonate. [Adapted from Refs 35 and 36.]

has been reported for the oxidation of typical two-electron donors such as thiols (RSH) and thiolates (RS^-)^{38,39}:

Here, increasing the concentration of the substrate is associated with a reduction of the peroxynitrite lifetime, and the decay of peroxynitrite in (5) follows second-order kinetics.³⁸ The value of the rate constant of (5) depends on the thiol structure and varies within the range of $2.8 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$ for glutathione³⁸ to $\sim 2 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ for thiols and thiolates in proteins.³⁹

Hydrogen Peroxide

In pure aqueous solutions, hydrogen peroxide is quite stable and exists in the form of H_2O_2 , which is a very weak acid with $\text{p}K_a = 11.7$.⁴⁰ Two-electron oxidation reactions of hydrogen peroxide are typically very slow. For instance, the two-electron oxidation of glutathione by H_2O_2 at pH 7.4 occurs with the rate constant of $0.9 \text{ M}^{-1} \text{ s}^{-1}$.⁴¹

The transformation of H_2O_2 to highly reactive radicals can be initiated by traces of transition-metal ions.^{42,43} In 1876, Fenton demonstrated that mixing tartaric acid with H_2O_2 and low concentrations

of Fe(II) generates a colored product,⁴⁴ which was later identified as dihydroxymaleic acid, the oxidation product of tartaric acid.⁴⁵ Further studies have shown that the Fe(II)/ H_2O_2 system (Fenton reagent) efficiently oxidizes a variety of organic molecules.^{42,43} In neutral solutions, the catalytic effect of iron ions can be illustrated by the following simple scheme developed by Haber and Willstätter,⁴⁶ Haber and Weiss,^{47,48} and Baxendale and coworkers.^{49,50}

The reduction of H_2O_2 generates highly reactive hydroxyl radicals (Fenton reaction), which rapidly react with most organic molecules. The Fe(II) ions are regenerated by reduction of Fe(III) ions by superoxide radicals derived from the oxidation of H_2O_2 by $\cdot\text{OH}$ radicals. The direct reaction of $\text{O}_2^{\cdot-}$ (or $\text{HO}_2^{\cdot}$) with H_2O_2 (Haber–Weiss reaction) is very slow and its rate constant is in the range $0.1\text{--}0.5 \text{ M}^{-1} \text{ s}^{-1}$.⁵¹

In 1932, at the same time as Haber and Weiss were investigating the Fe(II/III)/ H_2O_2 system, Bray

and Gorin⁵² proposed an alternative mechanism of the Fenton reaction:

where FeO^{2+} is “ferryl,” an iron(IV) species, which has a “free $\cdot\text{OH}$ -radical-like” reactivity. Over 70 years after Haber’s group proposed hydroxyl radicals as intermediates in the Fenton system, considerable controversy remains about the existence of free hydroxyl radicals.^{42,43} However, a full discussion of this problem is beyond the scope of this article.

Further studies have demonstrated that diverse metal ions and their complexes in lower oxidation states such as Cu(I), Ti(III), Cr(II), and Co(II) in mixtures with H_2O_2 are characterized by oxidative properties similar to those of the Fenton reagent.^{42,43} Extensive studies of “Fenton-like” reagents have shown that typical reactions of metal complexes with H_2O_2 do not occur via an outer-sphere electron transfer mechanism and involve the formation of the intermediate complexes:

These complexes can produce $\cdot\text{OH}$ radicals or higher oxidation states of the metal (e.g., Fe(IV) and Cu(III)), which can exhibit “Fenton-like” reactivities with organic substrates.^{42,43}

Another set of problems is associated with complex formation between transition-metal ions and substrate molecules (e.g., DNA). Indeed, negatively charged DNA molecules can site-specifically bind positively charged metal ions (e.g., Fe^{2+}).⁵³ In this case, the Fenton reaction of H_2O_2 with the bound metal ions (or their complexes) generates reactive species (e.g., $\cdot\text{OH}$ and FeO^{2+}) in the vicinity of these sites, and the distributions of oxidatively modified nucleobases can differ from those generated by radiolytically generated $\cdot\text{OH}$ radicals. To address this problem, Tullius and coworkers have recommended the use of the $[\text{Fe(II)(EDTA)}]^{2-}/\text{H}_2\text{O}_2/\text{ascorbate}$ system.⁵⁴ Here, complex formation between Fe(II) and DNA is minimized by using negatively charged Fe(II) complexes with ethylenediaminetetraacetic acid (EDTA). Hydroxyl radicals produced by the $[\text{Fe(II)(EDTA)}]^{2-}/\text{H}_2\text{O}_2/\text{ascorbate}$ system and by ionizing radiation generate the same 2-deoxyribose damage the chemistry.⁵⁵ However, the damage of

DNA nucleobases by radiolytically generated $\cdot\text{OH}$ radicals is more efficient than damage of the sugar residues because the rates of $\cdot\text{OH}$ addition to nucleobases are higher than the rates of H-atom abstraction from 2-deoxyribose.^{56,57} In turn, addition of ascorbate, which can repair the nucleobase radicals via a reduction mechanism, enhances the relative yields of 2-deoxyribose damage in comparison with base damage.⁵⁸

Hypochlorous acid is a weak acid with $\text{p}K_a = 7.5$.⁵⁹ HOCl is capable of initiating two-electron oxidation reactions with proteins⁶⁰ and thiols. For instance, HOCl oxidizes glutathione at pH 5–9 with a rate constant $\geq 10^7 \text{ M}^{-1} \text{ s}^{-1}$,⁶¹ which is five orders of magnitude greater than the analogous rate constant with ONOOH.³⁸ Another important reaction is the oxidation of amines by HOCl to form chloramines.⁶² The rate constants of these reactions are typically two orders of magnitude smaller than those of thiols. For instance, the rate constant of the reaction of HOCl with taurine (2-aminoethanesulfonic acid) at pH 7 is $4.8 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$.⁶¹

In this reaction, taurine is released by isolated neutrophils in large amounts and is transformed to taurine chloramines, which retain their ability to react with thiol groups.⁶³

The reduction of HOCl by superoxide radicals (the analog of the Haber–Weiss reaction) is considered to be an efficient source of $\cdot\text{OH}$ radicals^{42,43}:

The rate constant of $\sim 7.5 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for this reaction is seven orders of magnitude greater than the constant for H_2O_2 (9).⁶⁴ The formation of $\cdot\text{OH}$ radicals in (13) has been confirmed using benzoate as a trap; the hydroxylation of this compound in the presence of HOCl and $\text{O}_2^{\cdot-}$ generates three isomeric hydroxybenzoates in the same ratio as the radiolytically generated $\cdot\text{OH}$ radicals.⁶⁵

The one-electron reduction of HOCl by metal ions (analog of the Fenton reaction) can potentially generate both hydroxyl and chlorine radicals⁶¹:

Figure 3 Chlorinated nucleobases generated in DNA by HOCl.

In the case of ferrocyanide, Fe(II)(CN)_6^{4-} , (14) produces $\cdot\text{OH}$ radicals in 27% yield as shown by the hydroxylation of benzoate to give a product distribution identical to that produced by radiolytically generated hydroxyl radicals.⁶⁶ The products of benzoate chlorination were not identified in these experiments.

Products of DNA Damage Produced by HOCl

The latter directly reacts with DNA to form *N*-chloramine derivatives of nucleobases.^{67,68} The heterocyclic NH groups are generally more reactive than the exocyclic NH_2 groups. For instance, the rate constant for reaction of HOCl with N1H of guanosine-5'-monophosphate ($k = 2.1 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$) is four orders of magnitude greater than for the reaction with the NH_2 group ($k = 2.4 \text{ M}^{-1} \text{ s}^{-1}$).⁶⁹ The *N*-chloramines of nucleobases are highly unstable and readily decompose to form a wide spectrum of the chlorinated nucleobases (Figure 3) including 8-chloro-2'-deoxyadenosine (5),^{70–73} 8-chloro-2'-deoxyguanosine (6),^{70,71} 5-chloro-2'-deoxycytidine (7),^{70,71,73,74} and 5-chloro-2'-deoxyuracil (8).^{75,76}

2.2.2 Radical Reactive Species

Persistent oxidative stress associated with chronic inflammation is associated with the overproduction of free oxyl radicals ($\text{O}_2^{\cdot-}$, $\text{CO}_3^{\cdot-}$, $\cdot\text{NO}_2$, $\cdot\text{OH}$).^{1–3,5,6} Among these radicals, $\text{CO}_3^{\cdot-}$, $\cdot\text{NO}_2$, and $\cdot\text{OH}$ are strong oxidizing agents, but only hydroxyl radicals^{56,57} and carbonate radical anions⁷⁷ can directly react with nucleic acid bases in DNA to produce irreversible damage.

Hydroxyl radicals are powerful oxidants with a standard reduction potential of $E^\circ = 1.9 \text{ V}$ versus NHE.⁷⁸ In alkaline solutions, the $\cdot\text{OH}$ radical ($\text{p}K_a = 11.9$) dissociates to its conjugate base $\cdot\text{O}^-$.⁷⁹

In reactions with organic molecules, $\cdot\text{OH}$ radical reacts as electrophile, whereas $\cdot\text{O}^-$ acts as a nucleophile. For instance, the addition of $\cdot\text{OH}$ to unsaturated bonds is typically fast; in contrast, $\cdot\text{O}^-$ does not add to unsaturated compounds. In the case of aromatic molecules with aliphatic side chains, $\cdot\text{OH}$ adds preferentially to the aromatic ring, whereas $\cdot\text{O}^-$ readily abstracts H atoms from aliphatic C–H bonds.⁷⁹

Some common methods of $\cdot\text{OH}$ -radical generation are (i) radiolysis of water, (ii) photolysis of appropriate compounds, and (iii) Fenton-type reagents.⁷⁹ Radiolysis of water generates a wide spectrum of reactive species:

where the numbers in parentheses are the *G* values, which represent the number of molecules formed per 100 eV energy absorbed by pure water.⁷⁹ In order to remove hydrated electrons and H atoms, experiments are typically conducted in solutions saturated with nitrous oxide that produce additional $\cdot\text{OH}$ radicals by reacting with e^-_{aq} ($k = 9.1 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$) and $\cdot\text{H}$ ($2.1 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$).⁷⁹

Photochemical methods of generating $\cdot\text{OH}$ radicals can be illustrated by the following equations⁷⁹:

An alternative method is to photoionize the appropriate compounds in aqueous solutions:

saturated with N₂O, which requires the conversion of e⁻_{aq} to [•]OH radicals (17). Hydroxyl radicals have relatively small molar extinction coefficients in the far UV spectral range ($\lambda_{\text{max}} = 230$ nm, $\epsilon = 530$ M⁻¹ cm⁻¹),⁸⁰ and the kinetics of [•]OH radicals is typically monitored by the appearance of product radicals that have characteristic absorption spectra.⁷⁹

The Carbonate Radical Anion

At pH > 0, the carbonate radicals exist in the form of CO₃^{•-}, because the conjugate HCO₃⁻ is a strong acid ($pK_a < 0$).⁸¹ The carbonate radical is a strong one-electron oxidant with a standard reduction potential⁸² of $E^\circ = 1.59$ V versus NHE, and can rapidly and selectively oxidize biomolecules by one-electron abstraction mechanisms.⁸³ These radicals rapidly abstract electrons from aromatic amino acids (tyrosine and tryptophan). However, reactions of CO₃^{•-} radicals with sulfur-containing methionine and cysteine are less efficient.^{84–86} Hydrogen-atom abstraction by carbonate radicals is generally very slow,⁸³ and their reactivities with amino acids are negligible.^{84–86} One-electron oxidation reactions mediated by CO₃^{•-} radicals can be monitored in real time by spectroscopic transient absorption methods (e.g., laser flash photolysis and pulse radiolysis) because CO₃^{•-} radicals have a characteristic absorption band at 600 nm ($\epsilon = 1970$ M⁻¹ cm⁻¹).⁸¹

Carbonate radical anions are commonly generated by the following methods: (i) oxidation of HCO₃⁻ anions (or CO₃²⁻ in alkaline solutions) either by radiolytically generated [•]OH radicals or by photochemically generated SO₄^{•-} radicals and (ii) photolysis of carbonate transition-metal complexes.⁸³ In typical pulse radiolysis experiments, the oxidation of HCO₃⁻ anions by [•]OH radicals (rate constant 8.5×10^6 M⁻¹ s⁻¹) is described by the following equation⁷⁹:

In our experiments, either steady-state^{87–91} or pulsed UV light (e.g., 308 nm XeCl excimer laser pulses)^{77, 92–94} photolysis methods were employed. In buffered solutions containing bicarbonate and persulfate anions, irradiation with UV light induces the dissociation of the S₂O₈²⁻ ions to sulfate radical anions SO₄^{•-}:

The latter is a strong one-electron oxidant with a standard reduction potential⁸² of $E^\circ = 2.43$ V versus NHE, which oxidizes HCO₃⁻ anions with the rate constant of 4.6×10^6 M⁻¹ s⁻¹.⁷⁷

However, these methods cannot be used at pH < 7.5 owing to the transformation of HCO₃⁻ to CO₂, which is not oxidized by [•]OH and SO₄^{•-} radicals. The photolysis of carbonatotetraminecobalt(III) complexes by steady-state or pulsed UV light allows overcoming this unfavorable pH effect and can be used to generate CO₃^{•-} radicals in a wide range of pH values (pH ~3–13)^{95,96}:

Our experiments have shown that CO₃^{•-} radicals, regardless of the method of generation, exhibit the same reactivities and generate the same oxidation products.⁹⁰

Nitrogen dioxide radicals are mild one-electron oxidants with a standard reduction potential of $E^\circ = 1.04$ V versus NHE.⁷⁸ In aqueous solutions, [•]NO₂ radicals typically react reasonably rapidly in free-radical reactions, but react more slowly by electron transfer mechanisms with appropriate electron donors and by addition to unsaturated bonds.^{83,97} In pure aqueous solutions (without substrates), the lifetimes of [•]NO₂ radicals are limited by dimerization to form nitrogen tetroxide ($k = 4.5 \times 10^8$ M⁻¹ s⁻¹)⁸³ that rapidly hydrolyzes ($k = 1 \times 10^3$ M⁻¹ s⁻¹)⁹⁸ to form nitrite and nitrate anions.

In aqueous solutions, [•]NO₂ radicals are commonly generated by two methods: (i) reduction of nitrate anions by hydrated electrons ($k = 9.7 \times 10^9$ M⁻¹ s⁻¹)⁷⁹

and (ii) oxidation of nitrite anions by [•]OH radicals ($k = 1.0 \times 10^{10}$ M⁻¹ s⁻¹)⁷⁹ or SO₄^{•-} radicals

($k = 8.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$)⁸³:

Absorption of $\text{}^{\bullet}\text{NO}_2$ radicals in the spectral range 300–500 nm is weak ($\lambda_{\text{max}} = 400 \text{ nm}$, $\varepsilon = 200 \text{ M}^{-1} \text{ cm}^{-1}$) and reactions of these radicals are typically monitored by the appearance of the absorption bands of the reaction product.⁷⁹

Superoxide Radicals

In neutral aqueous solutions, $\text{O}_2^{\bullet-}$ is the major form because the pK_a of the conjugated acid (i.e., the hydroperoxyl radical $\text{HO}_2^{\bullet}$) has a value of 4.8.⁹⁹ In contrast to organic peroxy radicals $\text{RO}_2^{\bullet}$, which exhibit only oxidizing properties, the $\text{O}_2^{\bullet-}$ radicals have both reducing and oxidizing properties. The standard reduction potential of O_2 is of $E^\circ(\text{O}_2/\text{O}_2^{\bullet-}) = -0.16 \text{ V}$ versus NHE.⁷⁸ In agreement with this potential, $\text{O}_2^{\bullet-}$ radicals rapidly reduce quinones and other appropriate acceptors by one-electron transfer mechanisms.⁹⁹ Combination reactions of $\text{O}_2^{\bullet-}$ radicals with other free radicals play an important role in the chemistry of the superoxide. One of these reactions is the extremely fast combination of $\text{O}_2^{\bullet-}$ and $\text{}^{\bullet}\text{NO}$ radicals to form the highly toxic peroxynitrite (1).

In aqueous solutions, superoxide radicals are commonly produced by the reduction of oxygen by radiolytically or photochemically generated hydrated electrons. These reactions occur with the diffusion-controlled rate constant of $2 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ ⁹⁹:

In biochemical experiments, continuous fluxes of superoxide radicals are generated by the enzymatic oxidation of xanthine catalyzed by xanthine oxidase.¹⁰⁰ In this process, electrons abstracted from xanthine by xanthine oxidase are transferred to oxygen molecules to form superoxide radicals. In pure aqueous solutions, the lifetimes of $\text{O}_2^{\bullet-}$ radicals are determined by their dismutation to O_2 and H_2O_2 molecules with the rate constant⁹⁹ of $5.2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ at pH 7 and become significantly shorter in the presence of SOD (2).^{18,19}

Superoxide radicals absorb light in the far UV spectral region ($\lambda_{\text{max}} = 243 \text{ nm}$, $\varepsilon = 2.35 \times 10^3$

$\text{M}^{-1} \text{ cm}^{-1}$),⁹⁹ which is a spectroscopically inaccessible region because of the strong absorbance of biomolecules in this range of wavelengths. An effective method for monitoring $\text{O}_2^{\bullet-}$ radicals in laser flash photolysis and pulse radiolysis experiments is the fast reduction of tetranitromethane ($k = 1.9 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) to the nitroform anion ($\lambda_{\text{max}} = 350 \text{ nm}$, $\varepsilon = 14.6 \times 10^3 \text{ M}^{-1} \text{ cm}^{-1}$).¹⁰¹

In contrast, other $\text{RO}_2^{\bullet}$ radicals have only oxidizing properties and do not react with tetranitromethane.¹⁰²

3 REACTION KINETICS OF ROS/RNS RADICALS WITH DNA

3.1 Radical Addition/Hydrogen-Atom Abstraction

3.1.1 Kinetics of DNA Damage by $\text{}^{\bullet}\text{OH}$ Radicals

The reactions of highly reactive hydroxyl radicals with DNA occur by two major mechanisms: (i) $\text{}^{\bullet}\text{OH}$ radical addition to nucleobases, which can produce base modifications and (ii) H-atom abstraction from 2-deoxyribose residues, leading to DNA strand breaks.^{54, 56–58, 103} The $\text{}^{\bullet}\text{OH}$ -addition reactions do not show any base-sequence selectivity, because they are extremely fast and occur with close to diffusion-controlled rate constants.⁵⁶ The rate constants of H-atom abstraction from the sugar residues in double-stranded DNA are typically smaller by one order of magnitude than the rate constants for $\text{}^{\bullet}\text{OH}$ -addition reactions.⁵⁷ The H-atom abstractions generate C-centered radicals of 2-deoxyribose. Further fragmentation of these intermediates results in cleavage of 2-deoxyribose and the formation of the “direct” DNA strand breaks. In DNA sequences with 5'- or 3'-ends labeled by a radioactive isotope of phosphorus (^{32}P), these strand breaks can be visualized and quantitated by denaturing polyacrylamide gel electrophoresis with a one-base resolution.⁵⁴ In turn, DNA containing oxidatively modified nucleic acid bases can be cleaved at the sites of modification by hot piperidine or by enzymatic treatment and detected as strand breaks by gel electrophoresis.⁵⁸

Hydroxyl radicals can abstract all seven H atoms of 2-deoxyribose.⁵⁴ The substitution of 2-deoxyribose hydrogen atoms by deuterium affects the yields of strand breaks in double-stranded DNA in a site-specific manner with the following preference of $\cdot\text{OH}$ radical attack: $\text{H}5' > \text{H}4' > \text{H}3' \approx \text{H}2' \approx \text{H}1'$.¹⁰⁴ This trend of reactivity correlates with the solvent accessibility of the different deoxyribose H atoms. Correlation of the solvent-exposed areas of the deoxyribose H atoms with the efficiencies of direct strand cleavage induced by $\cdot\text{OH}$ radicals provides insights into the structures of DNA and DNA–protein complexes.^{103,105} Using this method (footprinting), the binding sites of the proteins are revealed by the nucleotides that are not cleaved by $\cdot\text{OH}$ radicals because these sites are shielded by the bound proteins. Typically, $\cdot\text{OH}$ radicals are generated by the $[\text{Fe}(\text{II})(\text{EDTA})]^{2-}/\text{H}_2\text{O}_2/\text{ascorbate}$ system, which efficiently generates direct strand breaks by the base-sequence-independent cleavage of the 2-deoxyribose moieties.⁵⁵ Another method of hydroxyl radical generation for footprinting purposes involves the spontaneous homolysis of peroxyxynitrite in neutral solutions (3)¹⁰⁶ and the radiolysis of water by synchrotron radiation.¹⁰⁷ These methods generate similar DNA cleavage patterns.

Hydroxyl radical footprinting has also been successfully used to study the structural properties of nucleosome core particles, which are the basic repeating units of chromatin.¹⁰⁸ Nucleosome core particles are assembled from an octamer consisting of two copies of four histone proteins, H2A, H2B, H3, and H4, and a 147-base pair double-stranded DNA molecule. High-resolution X-ray studies of the structures from different organisms have revealed that the 147 base pairs of DNA are wrapped as 1.65 left-handed superhelical turns around the histone octamer.¹⁰⁹ In these structures, the tight interactions between the rigid framework of the histone core at 14 independent DNA binding locations induce a massive distortion of the normal DNA structure. These interactions change the accessibility of the individual DNA bases to hydroxyl radicals in the core region, which results in the appearance of strong periodic patterns of direct DNA strand cleavage patterns.^{110,111} Hydroxyl radical footprinting of the nucleosome core particles in solution has shown that distortions induced by the interactions of DNA with the histone core are not uniform, and that the

region of DNA containing approximately the central 30 base pairs of DNA has a periodicity of 10.7 bases per turn, whereas DNA segments on either side of this region have periodicities of 10.0 bases per turn.¹¹⁰

In biological systems, DNA damage by free $\cdot\text{OH}$ radicals is highly restricted. The electrophilic $\cdot\text{OH}$ radicals rapidly react with the most organic molecules, and $\cdot\text{OH}$ radicals will be efficiently intercepted before they can arrive at the DNA molecule via diffusive processes. The average distance of diffusion of randomly generated $\cdot\text{OH}$ radicals in cells is about 30 Å. Highly reactive species (e.g., $\cdot\text{OH}$ and FeO^{2+}) can be generated by metal ions bound to DNA (e.g., Fe^{2+}) because hydrogen peroxide is a relatively small, reactive, and freely diffusing molecule in biological systems.

3.1.2 Products of DNA Damage Generated by $\cdot\text{OH}$ Radicals

The highly reactive hydroxyl radicals produce oxidative modifications of 2-deoxyribose residues and all four natural DNA bases.^{54,58,112,113} The dominant reactions of $\cdot\text{OH}$ radicals with DNA bases occur via their addition to unsaturated bonds, except in the case of thymine and guanine where hydrogen-atom abstraction from the methyl group of thymine^{112,114} or from the exocyclic amino group of guanine occurs.¹¹⁵

Thymine

The addition of $\cdot\text{OH}$ radicals to the 5,6 double bond of thymine (**9**) generates 5-hydroxy and 6-hydroxy C-centered radicals, which can potentially abstract hydrogen atoms from adjacent 2-deoxyribose residues to produce direct strand breaks.⁵⁸ These C-centered radicals are short-lived because of their rapid reactions with molecular oxygen to form peroxy radicals, which further lead to diverse products that include *cis*- and *trans*-5,6-dihydroxy-5,6-dihydrothymidine (**10**), *N*¹-(2-deoxy- β -D-erythro-pentafuranosyl)-5-hydroxy-5-methylhydantoin (**11**), and *N*-(2-deoxy- β -D-erythro-pentafuranosyl)formamide (**12**) (Figure 4).¹¹² The H-atom abstraction from the methyl group results in the formation of the C-centered 5-(uridiny)methyl radical ($\text{U}\cdot\text{CH}_2$), which can potentially react with guanine bases to form intrastrand cross-links.^{116–119} The C-centered

Figure 4 Oxidative products generated by the oxidation of thymine (**9**), cytosine (**15**), and adenine (**19**) by hydroxyl radicals.

U- $\cdot\text{CH}_2$ radicals rapidly react with O_2 to form peroxyl radicals, which further leads to the formation of 5-(hydroxymethyl)-2'-deoxyuridine (**13**) and 5-formyl-2'-deoxyuridine (**14**) (Figure 4).¹¹²

Cytosine

Addition of $\cdot\text{OH}$ radicals to the 5,6 double bond of cytosine (**15**) makes the exocyclic amino group of cytosine more susceptible to hydrolytic deamination.⁵⁸ This leads to a wide spectrum of oxidative modifications, which include both oxidatively modified cytosine and uracil arising from deamination reactions. These products include 5-hydroxy-5,6-dihydrocytosine (**16**), 5-hydroxy-5,6-dihydrouracil (**17**), and 5,6-dihydroxy-5,6-dihydrouracil (**18**) (Figure 4).^{57,58}

Adenine

Hydroxyl radicals generate two well-known products arising from the hydroxyl radical addition to the C8 position of adenine (**19**): 8-oxo-7,

8-dihydro-2'-deoxyadenosine (**20**) and 4,6-diamino-5-formamidopyrimidine (**21**) (Figure 4).^{58,112}

Guanine is the most easily oxidizable natural DNA base.^{120–122} The reactions of guanine bases with ROS/RNS generated at sites of inflammation are particularly important and are discussed in detail in the following sections of this article.

3.1.3 Intrastrand G–T Cross-Links Generated by $\cdot\text{OH}$ Radicals

Intrastrand cross-links, which involve a covalent bond between adjacent guanine and thymine residues on the same strand in oligonucleotides (the so-called tandem lesions), were originally discovered by Box and coworkers (Figure 5).^{116–119} These tandem lesions were generated by radiation-induced $\cdot\text{OH}$ radicals in oxygen-free solutions. The G–T intrastrand cross-links involve covalent bonds between guanine C8 and the C5 methyl group

Figure 5 Tandem lesions generated in DNA by hydroxyl radicals.

of thymine or a 5-methyl group at the C5 position of cytosine. These cross-links arise from the formation of C-centered 5-(uracil)methyl radicals ($\text{U}^{\bullet}\text{CH}_2$).^{123,124} The independent generation of $\text{U}^{\bullet}\text{CH}_2$ radicals by photolysis of 5-(phenylthiomethyl)-2'-deoxyuridine also results in the formation of these G–T tandem lesions, which supports this conclusion. The $\text{U}^{\bullet}\text{CH}_2$ radicals rapidly react with O_2 , thereby suppressing the formation of the covalent bond between $\text{U}^{\bullet}\text{CH}_2$ and G–C8.¹²⁵ The formation of GC tandem lesions (**23**) generated by hydroxyl radicals has been reported by Wang and coworkers.^{126–128} The mechanism is similar: the 6-hydroxy-5,6-dihydrocytosyl radical produced by $\bullet\text{OH}$ radical adds to the C8 position of guanine and, after dehydration, the GC lesion is formed. Interestingly, O_2 does not seem to interfere with the formation of interstrand tandem lesions between adjacent A and T bases (**24**) (Figure 5).^{129,130} In order to account for this effect, it was proposed that the reaction of the $\text{U}^{\bullet}\text{CH}_2$ radicals with O_2 is reversible; this is possible since the forward bimolecular rate constant $k(\text{O}_2) = 2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, whereas the

first-order rate constant of the decomposition of the peroxy radical is $k_{-}(\text{O}_2) = 3.4 \text{ s}^{-1}$. Thus, the small transient concentrations of $\text{U}^{\bullet}\text{CH}_2$ radicals can account for the formation of such tandem lesions even in the presence of O_2 .^{124,129,130}

3.2 One-Electron Oxidation

3.2.1 Thermodynamics of DNA Oxidation

Guanine is the most easily oxidizable natural DNA base. Pulse radiolysis experiments have shown that the reduction potential of guanine neutral radicals $\text{dG}(-\text{H})^{\bullet}$ (calculated from equilibria with reference radicals of known potentials) is equal to $E_7[\text{dG}(-\text{H})^{\bullet}, \text{H}^+/\text{dG}] = 1.29 \text{ V}$ versus NHE at pH 7.¹³¹ The values of E_7 for the other three nucleosides (N) increase as follows: $\text{dG} < \text{dA} < \text{dC} \sim \text{dT}$ (Table 2). The values of the standard reduction potentials^{131,132} $E^{\circ}(\text{dN}^{+}/\text{dN})$ calculated from the experimental plots of E_{pH} versus pH are systematically higher than the E_7 values and correlate

Table 2 Reduction potentials (vs NHE) of nucleoside radicals.

Nucleoside	E_7^a (V)	$E^o,^b$ (V)	$E_{CV}^o,^c$ (V)
dG	1.29	1.58	1.49
dA	1.42	2.03	1.96
dT	~1.6	—	2.11
dC	~1.7	—	2.14

^aObtained for pairs dN(-H)[•], H/dN in aqueous solutions (pH 7) by pulse radiolysis methods.^{131,132}

^bCalculated from the dependence of E_{pH} versus pH.^{131,132}

^cObtained from potentials measured by cyclic voltammetry in acetonitrile.¹³³

with the values obtained by cyclic voltammetry in acetonitrile.¹³³ Thus, the thermodynamic characteristics of one-electron oxidation of nucleic acid bases are consistent with the preferential oxidation of guanine bases by one-electron mechanisms.

3.2.2 Effects of Base Sequence on the One-Electron Oxidation of Guanine

In double-stranded DNA, the one-electron oxidation of G-bases depends on the base-sequence context. For example, oxidatively generated guanine damage is more abundant at the 5'-G in 5'-...GG... sequences and the first two 5'-guanines in the 5'-...GGG... sequences than in isolated guanines, that is, at guanines that are not flanked by other guanines. These effects are attributed to the redistribution of guanine radicals among the contiguous guanine bases by the hole hopping mechanism that occurs after the initial electron abstraction steps (hole injection); it is further assumed that the subsequent chemical reactions that lead to product formation at a particular guanine in runs of GG or GGG depend on the probability that the hole is localized at that guanine (see **Charge Transfer in DNA**). These mechanisms can successfully account for the sequence-dependent distributions of guanine damage initiated by one-electron oxidants generated by the photosensitization of metal complexes,^{134,135} anthraquinones,^{136,137} naphthalimides,¹³⁸ riboflavin,^{139,140} 4'-pivaloyl derivatives,^{141,142} cyanobenzoyl- and cyanobenzophenone-substituted 2'-deoxyuridine,^{143,144} and other chemical one-electron oxidants.^{145,146} Saito and coworkers demonstrated that the probability of formation of oxidatively generated guanine damage within runs of contiguous guanines varies according to 5'-G < 5'-GG <

5'-GGG. This trend is consistent with the calculated gas-phase ionization potentials of each guanine in the case of 5'-G (flanked on both sides by bases other than guanine), 5'-GG, and 5'-GGG sequence contexts.^{139,140,147–149}

3.2.3 Reaction Kinetics of the Oxidation of Guanine by Carbonate Radicals

In our laboratory, we have extensively used laser kinetic spectroscopy methods to monitor the kinetics of one-electron oxidation of guanine in DNA by CO₃^{•-} radicals.^{77,90,92,94,150} In typical experiments, we use the transient absorbance properties of radical intermediates. The CO₃^{•-} radical has a characteristic absorption spectrum with a maximum at 600 nm. In the presence of guanine, either in the form of a nucleoside or incorporated in oligonucleotides, the decay of this band is correlated with the rise of another narrow absorption band with a maximum near 315 nm. This band is characteristic of the guanine radical cation G^{•+} or the guanine neutral radical G(-H)[•] species, which have similar absorption spectra¹⁵¹ and which are generated by the oxidation of G by carbonate radical anions. However, in double-stranded DNA, deprotonation of the G^{•+} radical cations occurs on submicrosecond timescales,^{152,153} while the kinetics of oxidation of G in DNA by CO₃^{•-} radicals occurs on millisecond time scales. Thus, the 315-nm absorbing species in the microsecond to millisecond time range can be predominantly assigned to the neutral G(-H)[•] radicals.^{77,90,92,94,150}

The CO₃^{•-}-mediated oxidation of guanines in single-stranded and double-stranded oligonucleotides 20–35 nucleotides in length containing single G (flanked by bases other than G) and guanines grouped as contiguous GG and GGG sequences was monitored by transient absorption laser kinetic spectroscopy.^{77,90,92,94,150,154} In these experiments, the decay of CO₃^{•-} radicals occurs via two competitive reactions: (i) oxidation of G-bases in DNA associated with the growth of the G(-H)[•] absorption band at 315 nm and (ii) the bimolecular recombination of CO₃^{•-} radicals

$$(k_r = 1.3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1})^{77}:$$

The rate constants of G-base oxidation (k_g) in (33) were obtained by fitting the integrated forms of the kinetic equation describing the decay of $\text{CO}_3^{\cdot-}$ radicals to the experimental kinetic decay curves of $\text{CO}_3^{\cdot-}$ recorded at different concentrations of double-stranded oligonucleotides and $\text{CO}_3^{\cdot-}$ radicals:

$$-\text{d}[\text{CO}_3^{\cdot-}]/\text{d}t = k_g [\text{G-DNA}] [\text{CO}_3^{\cdot-}] + 2k_r [\text{CO}_3^{\cdot-}]^2 \quad (35)$$

Regardless of the number or distributions of guanines in these double-stranded and single-stranded oligonucleotides, the rate constants of G-oxidation by $\text{CO}_3^{\cdot-}$ radicals thus obtained exhibited only small variations within the narrow range of $k_g = (1.5 - 3.0) \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$. These results show that solvent exposure of guanine G-sites, which in duplex **1d** with two G bases near the duplex ends is greater than in duplex **2d** with two internal G's, does not strongly control the initial rates of oxidation of guanine by $\text{CO}_3^{\cdot-}$ radicals (Figure 6). Thus, the one-electron oxidation of G-bases in DNA by $\text{CO}_3^{\cdot-}$ radicals significantly differs from the hydrogen-atom abstraction from 2-deoxyribose residues by $\cdot\text{OH}$ radicals, where solvent exposure controls the reaction yield.¹⁰⁴ The rate constant k_g of guanine oxidation by $\text{CO}_3^{\cdot-}$ radicals exhibits a very weak temperature dependence with activation energies of $7 \pm 3 \text{ kJ mol}^{-1}$. The lack of dependence of the rate constant on sequence context and the small activation energy indicates that the one-electron oxidation of guanine in DNA by $\text{CO}_3^{\cdot-}$ radicals occurs via an inner-sphere mechanism of electron transfer,^{94,150} which was proposed earlier for the one-electron oxidation of diverse organic molecules such as ascorbate, tryptophan, cysteine, and methionine by $\text{CO}_3^{\cdot-}$ radicals.¹⁵⁵ The mechanisms of outer/inner sphere electron transfer reactions in chemistry and biology have been extensively discussed by Marcus and Sutin.¹⁵⁶

Figure 6 The net rate constants of guanine oxidation in DNA duplexes by B[a]PT⁺ radicals (k_g) and bimolecular rate constants of DNA oxidation by $\text{CO}_3^{\cdot-}$ radicals (k_g). [Reprinted with permission from Ref. 94. Copyright 2008 American Chemical Society.]

3.2.4 Comparison with Aromatic Radical Cations

An outer-sphere electron transfer mechanism is expected in one-electron abstraction reactions from guanine by rigid aromatic radical cations.^{157–159} Indeed, the rate constants of oxidation of guanines in DNA by the pyrene derivative 7,8,9,10-tetrahydroxytetrahydrobenzo[a]pyrene (B[a]PT), a bulky and rigid aromatic molecule, do depend on the base-sequence context,^{94,150} in agreement with the Saito model.^{139,140,147} In these experiments, the selective excitation of the pyrenyl residue of B[a]PT by intense 355-nm nanosecond laser pulses yields free-radical products by a two-photon mechanism¹⁶⁰:

In air-equilibrated solutions, the hydrated electrons are rapidly trapped by molecular oxygen (31), while the BPT^{*+} radicals can oxidize guanine in DNA. Reactions of one-electron oxidation mediated by BPT^{*+} radicals can be monitored in real time by laser flash photolysis because these radicals have a characteristic absorption band at 455 nm.^{160,161}

The $\text{B}[a]\text{PT}$ molecules form noncovalent intercalation complexes with double-stranded DNA¹⁶² and with oligonucleotides.¹⁶³ The photoionization of $\text{B}[a]\text{PT}$ can occur either in solution or within a DNA complex. The fractions of $\text{B}[a]\text{PT}$ molecules in DNA complexes (ϕ) can be determined by examining the fluorescence decay profiles¹⁶⁴ because the fluorescence of BPT is strongly quenched by neighboring bases in DNA complexes.^{162,163} In 100-mM aqueous solutions of double-stranded oligonucleotides, under conditions where the concentrations of $[\text{BPT}] \ll [\text{DNA nucleotides}]$, most of the BPT molecules are bound to the DNA ($\phi = 0.8\text{--}0.9$).⁹⁴ In such solutions, the decay of the $\text{B}[a]\text{PT}^{*+}$ radicals exhibits a non-exponential decay profile and can be described by a sum of two-exponentials with first-order decay rate constants k_1 and k_2 and relative amplitudes a_1 and a_2 . The analysis of these decay profiles can be simplified by using the mean rate constant of $\text{B}[a]\text{PT}^{*+}$ radical decay: $k_a = a_1k_1 + a_2k_2$. A net overall rate constant of oxidation of guanines (k_G) in a given DNA duplex by $\text{B}[a]\text{PT}^{*+}$ radicals has been defined as follows: $k_G = k_a - k_0$, where k_0 is the rate constant of the decay of $\text{B}[a]\text{PT}^{*+}$ in duplex **6d** without any guanine bases.

The difference between the effects of base-sequence context on the rate constants of guanine oxidation by $\text{B}[a]\text{PT}^{*+}$ (k_G) and $\text{CO}_3^{\cdot-}$ (k_g) radicals in duplexes **1d–5d** is of significant interest for understanding the mechanisms of one-electron oxidation of guanine by different oxidants⁹⁴ (Figure 6). The value of k_G strongly depends on base-sequence context. For instance, the value of k_G for duplex **3d** (GG sequence) is larger by a factor of ~ 2.6 than in the case of duplex **2d** which has two nonadjacent guanines. In the duplex **5d**, which has a single contiguous GGG sequence, the value of k_G is larger by a factor of ~ 4.1 than in the case of duplex **4d** with three noncontiguous guanines. The value of k_G for duplex **4d**, which

has three guanines separated from one another, is about 20% greater than for duplex **2d** which has two noncontiguous guanines. These results are consistent with the Saito model,^{139,140,147–149,165} which predicts that guanines in contiguous runs of two or three guanines are more easily oxidized by one-electron oxidation mechanisms than isolated guanines in double-stranded DNA.

These rules, however, are not applicable if the guanines are positioned at or near the ends of oligonucleotide duplexes. For example, the k_G value for the sequence **1d** with isolated guanines near the ends in an AGA sequence contexts is similar to that in the GGG sequence context in the inner region of duplex **5d**. According to Saito *et al.*,¹³⁹ the oxidation of guanine in an AGA sequence context in the inner region of the duplexes is ~ 7 times smaller than that in a GGG sequence context.¹³⁹ The unexpectedly high value of k_G for guanine in the AGA sequence context is attributed to end effects rather than to sequence effects. Similarly, the k_G value for G in an isolated TGT sequences in duplex **4d** is 4 times smaller than that in the GGG sequence of duplex **5d**, which is in agreement with the Saito model. In contrast to the results obtained with $\text{B}[a]\text{PT}^{*+}$ radicals as the one-electron oxidants of guanine (Figure 6), the rate constants of the G-oxidation by $\text{CO}_3^{\cdot-}$ radicals in the same duplexes (**2d–5d**) with single G and contiguous GG and GGG sequences are close to each other (Figure 6).

The different base-sequence dependence of k_g (or k_G) in sequences **2d–5d** when $\text{CO}_3^{\cdot-}$ or $\text{B}[a]\text{PT}^{*+}$ radicals are used as the one-electron oxidants of guanine can be accounted for by considering the Marcus relationship describing the dependence of the rate constant on the free energy (ΔG^0) and reorganization energy (λ) of electron transfer¹⁵⁶:

$$k_{\text{el}} = (\lambda RT)^{-1/2} \exp[-(\Delta G^0 + \lambda)^2 / 4\lambda RT] \quad (38)$$

The $\text{CO}_3^{\cdot-}/\text{CO}_3^{2-}$ redox couple is characterized by a very small self-exchange rate constant ($k \sim 0.4 \text{ M}^{-1} \text{ s}^{-1}$), and the internal reorganization energy λ is therefore relatively high.¹⁶⁶ Whenever $\lambda > -\Delta G^0$, the electron transfer rate constant becomes less sensitive or even insensitive to small differences in ΔG^0 , as is the case for the G, GG, and GGG sequence contexts, thus explaining why the differences in k_g for $\text{CO}_3^{\cdot-}$ radicals is small. In the case of rigid aromatic radical cations, $\lambda < -\Delta G^0$ and k_G is now sensitive to changes in

the ΔG° values (Figure 6). Therefore, the k_G values shown in Figure 6 are consistent with the Saito model.^{139,140,147–149,165}

On the other hand, the high value of k_G (B[a]PT^{•+}) for duplex **1d** (Figure 6) is not consistent with the Saito model. This effect is attributed to the fraying of the ends of the oligonucleotide duplexes that enhances exposure of G near the ends to the aqueous solvent.¹⁶⁷ Increasing the solvent exposure of guanine to water is associated with the enhanced hydration of guanines, which is known to lower the reduction potentials of the guanine radicals.^{168–173} Thus, the lower ionization potential of guanine (or change in ΔG° in (38)) gives rise to a higher rate constant of oxidation at the ends of duplexes than in the inner regions of the duplexes.

In summary, the initial oxidative one-electron transfer reactions between guanine and different oxidants can be either sensitive or insensitive to base-sequence context, and can also depend on the exposure of the guanines in double-stranded DNA to the aqueous solvent environment.

3.2.5 Effects of Oxidant Charge and Solvent Exposure on the Distributions of Guanine Lesions in DNA

In Section 3.2.4, we focused on values of the rate constants of the initial one-electron transfer rates from guanine in DNA to different oxidants and their dependence on base-sequence context. Most of the experimental literature on this subject is based on measurements of the end products of this initial step, mostly hot alkali-labile lesions. However, as discussed elsewhere,^{94,150} the base-sequence dependence of the initial electron transfer step and the sequence dependence of the final product distributions are not necessarily the same. While much more research will be needed to resolve this issue in a satisfactory manner, it is of interest to review the presently available information on this subject.

A series of one-electron oxidants including a negatively charged $\text{CO}_3^{\bullet-}$ radical,¹⁷⁴ a neutral photoexcited riboflavin,¹⁷⁵ and a positively charged B[a]PT^{•+} radical cation¹⁶⁰ were utilized to explore the effects of charge and solvent exposure on the localization of the final oxidatively generated guanine damage at different sites in DNA.^{94,150} The

Figure 7 Distributions of alkali-labile lesions generated by $\text{CO}_3^{\bullet-}$ and B[a]PT^{•+} radicals, and by photoexcited riboflavin, in a DNA duplex with noncontiguous guanines (G₁, G₂, G₆, G₇) and a sequence of three contiguous guanines (G₃, G₄, G₅) in the central region of the duplex. The complementary strand is not shown. [Reprinted with permission from Ref. 94. Copyright 2008 American Chemical Society.]

duplex **7d** was designed for this purpose (Figure 7); it contains two single noncontiguous guanines near each of the two ends of the duplexes (G₁, G₇) and two single guanines in the interior of the duplexes (G₂, G₆) separated by single T bases from the central contiguous G₃G₄G₅ sequence (Figure 7). The distribution of oxidatively generated damage in this sequence, determined by the standard hot-alkali high-resolution gel electrophoresis method,⁹⁴ is also depicted in Figure 7. In the case of oxidation by $\text{CO}_3^{\bullet-}$ radicals, the extent of cleavage is significantly higher at the guanines positioned near the ends of the duplexes (G₁ and G₇) than cleavage at the other single guanines in the interior of the duplexes (G₂ and G₆) as well as at the contiguous G₃G₄G₅ guanines. The preponderance of damage at the ends of the duplexes is consistent with the higher rate constant of one-electron oxidation of guanine (Figure 6). The extent of damage at the inner guanines is consistently smaller than the

damage at the ends of the duplexes. In contrast, the oxidation of the contiguous G₃G₄G₅ sequences is most efficient when the B[a]PT^{•+} radicals or riboflavin are employed as the oxidants (Figure 7). The cleavage efficiencies are the highest at G₄ in the 5'...TG₃G₄G₅T... sequence context in both cases. It is noteworthy that, in the case of the initial oxidation by the CO₃^{•-} radicals, the relative distributions of damage among the individual bases in the 5'...TG₃G₄G₅T... sequence and the lower damage at G₂ and G₆ than at G₄ qualitatively resemble the distributions of damage in the case of B[a]PT^{•+} and riboflavin. Thus, while the distribution of the oxidized hot alkali-labile guanines is in agreement with the Saito model,^{139,140,147–149,165} the rate constant of one-electron oxidation by CO₃^{•-} of guanine in duplex **7d** is not consistent with the predictions of this model.

3.2.6 Redistribution and Localization of Holes at Guanine Sites

This apparent discrepancy can be accounted for by considering the distribution of holes among contiguous guanines once holes are injected into the

duplex. These holes can migrate from guanine to guanine within the duplex across bridging T bases as long as the donor and acceptor are close enough to each other.^{176–178} Ultimately, the distributions of holes among the different guanines in a duplex equilibrate at the different sites according to the relative redox potentials at each individual guanine. Thus, in contiguous ...GG... or ...GGG... sequences^{139,140,147–149,165} and the solvent-exposed guanines at the ends of the duplexes, the holes will tend to have higher probabilities of localization at the sites characterized by the lowest values of ΔG° .^{94,150} When some of the guanines are too far apart in the duplex for efficient transfer to occur, hole equilibration occurs according to the same principle in contiguous ...GG... and ...GGG... sequences. This redistribution of the hole density apparently occurs before the subsequent chemical reactions take place, and thus the ultimate product distributions are expected to mirror the distributions of hole densities.^{94,150}

These effects on reactivity and cleavage patterns of contiguous guanines were further evaluated in different duplexes within the inner regions of duplexes **8d**, **9d**, and **10d** (Figure 8). The inner ...GG... or ...GGG... regions were positioned further from the ends than in the case of duplex **7d**

Figure 8 Distributions of alkali-labile lesions generated by CO₃^{•-} radicals in different DNA duplexes (the complementary strands are not shown) with noncontiguous guanines G, and grouped as contiguous GG and GGG sequences. [Reprinted with permission from Ref. 94. Copyright 2008 American Chemical Society.]

(Figure 7) to ensure that end effects would not influence the distributions of damaged guanine bases in these longer duplex sequences. The levels of cleavage at all noncontiguous guanines G₂, G₃, and G₄ in **8d** are similar, thus indicating that end effects can be neglected in the observed product distributions at these guanines (Figure 8). The cleavage efficiencies are higher at the 5'-side guanine G₃ in the 5'...TG₃G₄T... sequence context of **9d** and at the central guanine G₄ in the 5'...TG₃G₄G₅T... sequence context of **10d** (Figure 8). In all cases, the least damage is observed at the 3'-side guanines. In the 5'...TG₃G₄G₅T... sequence context of duplex **10d**, the order of reactivities is G₄ > G₃ > G₅ (Figure 8). Since the oligonucleotide strands were ³²P-end labeled at the 5'-side in these experiments, care was taken to limit the fraction of damaged strands to no more than 20% in any given experiment. Otherwise, the distributions closer to the 3'-ends could be different from the true values whenever there is more than one damaged site per oligonucleotide sequence. Indeed, the cleavage patterns in duplexes **10d**, with the guanine-containing strand ³²P-end-labeled either at its 5'-end or at its 3'-end, were similar, thus ensuring that the cleavage patterns within the inner contiguous sequences shown in Figure 8 were not distorted. In summary, in runs of contiguous guanines, the distribution of holes at the different sites reflects the redox potentials of the individual guanines.^{139,140,147–149,165} These distributions are reflected in the patterns of oxidatively damaged oligonucleotides, revealed by treatments of the oxidatively damaged oligonucleotides with hot alkali solutions. Similar considerations explain the higher levels of damage observed for isolated guanines near the ends of the duplexes, which is explained by their greater exposure to the aqueous solvent and thus the lowering of the redox potential of these hydrated guanines.^{94,150} It follows that a sequence-dependent product distribution will be observed even if the initial electron transfer step from a guanine to a solution-borne oxidant itself is not sequence-dependent. After the initial hole injection, there is a redistribution of the hole among the available guanines in contiguous G sequences.^{94,150} Thus, hole injection and hole distribution events are not necessarily coupled to each other since the distribution of chemical end products primarily reflect the hole distribution (after sufficient time has elapsed for equilibration to occur) rather than hole injection.

However, this conclusion depends on the assumption that the chemical step, after the initial creation of the hole, is itself independent of base-sequence context. This is an assumption that needs to be verified experimentally.

3.2.7 Monitoring Hole Migration

The kinetics of electron transfer reactions in DNA hairpins containing a stilbenedicarboxamide photosensitizer was studied extensively by Lewis and coworkers who determined the rate constants of forward- and back-transfer from single G to a GG doublet and to a GGG triplet.^{178,179} It was found that the free energy values for these reversible hole transfer reactions are approximately -0.052 and -0.077 V, respectively. Using an electrochemical method,¹⁸⁰ Sistare *et al.* determined the rate constants of oxidation of isolated guanines versus 5'-guanines in a GG sequence context. In our own experiments, we have employed hole injection techniques, which are based on laser pulse-induced two-photon photoionization of the DNA base analog 2-aminopurine (2AP) that can be site-specifically inserted into any DNA sequence using automated DNA synthesis methods.^{176,181–185} The 2AP residues have a broad absorption maximum at 305 nm, well outside the DNA absorption band, and can be selectively excited using 308-nm intense nanosecond XeCl excimer laser pulses. These pulses induce efficient and selective photoionization of 2AP residues, thus allowing for the injection of holes into any DNA sequence of interest. The absorption of the first photon results in the formation of the 2AP singlet excited state (¹2AP) and the absorption of the second photon causes photoionization according to the following scheme:

The energy of two 308-nm photons is $E = 7.77$ eV (the sum of the energy of the first singlet excited state of 2AP (¹2AP) is $\Delta E_{00} = 3.74$ eV, and the energy of the 308-nm photon $E = 4.03$ eV), thus providing sufficient energy for the efficient photoionization of 2AP.¹⁸¹ The lifetime of the singlet excited state of 2-aminopurine (¹2AP)

in solution is ~ 10 ns and is sufficiently long for absorption of the second photon to occur within the same excimer laser pulse (halfwidth ~ 12 ns) as long as this pulse is sufficiently intense. In double-stranded DNA, the ^12AP lifetime is severely reduced owing to quenching by neighboring nucleobases.¹⁸⁶ Thus, the efficiency of two-photon photoionization of 2AP is significantly reduced in double-stranded DNA. Nevertheless, the efficiency of the two-photon ionization of 2AP in DNA is sufficient, and we have used this method extensively for injecting holes into double- and single-stranded oligonucleotides.^{176,181–185} Although the photoionization step initially produces the $2\text{AP}^{+\bullet}$ radical cation, it rapidly deprotonates so that the oxidizing species in most of these experiments was the $2\text{AP}(\text{-H})^\bullet$ neutral radical.¹⁸⁷

The kinetics of electron transfer phenomena in DNA when both the donor and acceptor are embedded within the same molecule are entirely different than in the case of solution-borne oxidants. In the latter case, the oxidant and DNA diffuse freely and encounter each other before the electron transfer reaction resulting in hole injection into the DNA molecule can occur. An example of intramolecular hole injection processes is the one-electron oxidation of guanine by $2\text{AP}(\text{-H})^\bullet$ radicals, both site-specifically positioned within a DNA duplex.¹⁷⁶ The kinetics of oxidation of G by $2\text{AP}(\text{-H})^\bullet$ radicals were found to follow first-order kinetics. The magnitudes of the electron transfer rate constant in DNA depend on the number of nucleobases positioned between the electron donor and the acceptor.^{176,188–190} The dependence of the rate constant k_{et} of guanine oxidation by the $2\text{AP}(\text{-H})^\bullet$ radicals on the distance r between the donor and acceptor (which is proportional to the number of intervening bases) is experimentally described by the following equation:

$$k_{\text{et}} = k^0 \exp(-\beta r) \quad (41)$$

where β is an attenuation parameter. Plots of the linearized form of (41) are shown in Figure 9. In the case of intervening thymines, the parameter $\beta = 0.4 \text{ \AA}^{-1}$, while in the case of intervening adenines $\beta = 0.12 \text{ \AA}^{-1}$ in double-stranded DNA.^{176,188–190} The shallow distance dependence of hole transfer rates through the adenine tracts is consistent with the data of Majima and coworkers,^{191,192} also obtained by laser kinetic spectroscopy. The base-sequence

Figure 9 Distance dependence of the one-electron transfer rate constants from guanine bases (G) to neutral $2\text{AP}(\text{-H})^\bullet$ radicals in double-stranded oligonucleotide duplexes separated by different numbers of bridging A or T bases. [Reproduced from Ref. 190. © Wiley-VCH Verlag GmbH & Co. KGaA, 2009.]

effects on the distance dependence of hole transfer in DNA and the effects of intervening bases have been the subject of extensive theoretical investigations and associated with two distinct mechanisms of hole transfer: (i) a two-center unistep superexchange induced hole transfer and (ii) a multistep hole transfer mechanism via hole hopping.^{193–195}

3.3 Reactions of Free Radicals in DNA: End Products of Guanine Reactions Initiated by One-Electron Oxidation

3.3.1 Cation and Neutral Forms of Guanine Radicals

The primary product of one-electron abstraction from guanine (**25**) is the guanine radical cation $\text{G}^{+\bullet}$ (**26**) (Figure 10). The spectrum of $\text{G}^{+\bullet}$ exhibits a sharp absorption band with a maximum at 312 nm and two broad, less intense bands near 385 and 510 nm. The spectrum of the conjugate neutral form $\text{G}(\text{-H})^\bullet$ (**27**) is very similar but differs from the spectrum of $\text{G}^{+\bullet}$ by a weak broad absorption in the spectral range 610–750 nm. Using this spectral difference, Candeias and Steenken have shown that the free nucleoside radical cation $\text{dG}^{+\bullet}$ is a weak acid with $\text{p}K_{\text{a}} = 3.9$.¹⁵¹ The deprotonation

Figure 10 Guanine radicals generated by one-electron oxidation or by the addition of hydroxyl radicals. [Adapted from Refs 151, 205, 206, 265.]

of $\text{G}^{+\bullet}$ is associated with a buildup of the $\text{G}(\text{H})^{\bullet}$ radical which is characterized by an absorption band at 625 nm. The kinetics of this band has been determined by pulse radiolysis experiments of the Kobayashi group: the deprotonation rate constant for the free nucleoside $\text{dG}^{+\bullet}$ was found to be equal to $1.8 \times 10^7 \text{ s}^{-1}$.¹⁵² In double-stranded DNA, depending on the position within a DNA strand, the rate constant of deprotonation ($\geq 3 \times 10^6 \text{ s}^{-1}$) is smaller than that of free $\text{dG}^{+\bullet}$.^{152,153}

The deprotonation of $\text{G}^{+\bullet}$ has been considered in terms of a release of the N1 proton and the formation of the $\text{G}(\text{N1-H})^{\bullet}$ tautomer (27).⁵⁶ On the basis of electron paramagnetic resonance (EPR) studies in aqueous solutions ($\text{pH} \leq 3$) at room temperature, coupled with a theoretical study, it was

concluded that the $\text{G}^{+\bullet}$ radical is protonated at N1 and is indeed deprotonated by the loss of the proton at N1 to form the $\text{G}(\text{N1-H})^{\bullet}$ neutral radical.¹⁹⁹ A similar mechanism probably applies at $\text{pH} > 3$ as well. The radical cation of 1-Me-dG does not have a proton at the N-1 position and has a pK_a of 4.7; in this case, deprotonation occurs via release of a proton from the exocyclic (N^2) amino group, which results in the formation of the $\text{G}(\text{N}^2\text{-H})^{\bullet}$ neutral radical. Thus, both the N1 and N^2 sites may, in principle, be deprotonated in the guanine neutral radical.¹⁵¹ On the basis of UV-visible spectroscopy in combination with EPR studies in frozen D_2O solutions at low temperatures, the $\text{G}(\text{N1-H})^{\bullet}$ (27) neutral radical form is dominant.²⁰⁰ In contrast, EPR/ENDOR (electron nuclear double resonance)

studies at low temperatures have shown that G(-H)[•] radicals generated by ionizing radiation in single crystals of 2'-deoxyguanosine 5'-monophosphate are present mostly in the G(N²-H)[•] form (**28**, **29**).^{201,202} Extensive density functional theory (DFT) calculations based on various tautomeric forms of G(-H)[•] suggest that these two radical forms that are close to one another in energy may coexist.^{200,203,204} In the gas phase, the *syn*-G(N²-H)[•] tautomer (**28**) is more stable than the anti conformer (**29**), and the *syn*-G(N²-H)[•] tautomer is more stable than the G(N1-H)[•] tautomer by ~4.5 kcal mol⁻¹. However, a similar analysis for the aqueous solution case suggests that the hydration of G(-H)[•] may reverse this order, with the G(N1-H)[•] being more stable than *syn*-G(N²-H)[•] by ~3.3 kcal mol⁻¹.²⁰⁰

The addition of [•]OH radicals to guanine generates isomeric radicals (Figure 10) which are not identical to the G^{•+}/G(-H)[•] species produced by typical one-electron oxidants, such as SO₃^{•-}, Br₂^{•-}, and CO₃^{•-}.^{90,92,151,205} The pulse radiolysis studies of the O'Neill^{206,207} and Steenken^{56,196} groups showed that the OH adducts of guanine resemble both reducing and oxidizing radicals. The main adducts formed in 60–70% yields are oxidizing radicals, which undergo a fast dehydration to form G(-H)[•] radicals. The structure of the oxidizing radicals have been assigned as 4-OH-G[•], which are derived from the addition of [•]OH radicals to the C4 position of guanine.¹⁹⁶ Recently, Chatgililoglu and coworkers revisited the addition of [•]OH radicals to guanine and reported that the oxidizing radicals are formed by the abstraction of a hydrogen atom from the exocyclic NH₂ group of guanine to form the G(N²-H)[•] tautomers (**28**, **29**) (Figure 10).¹¹⁵ They found that, at room temperature, these tautomers are unstable and rapidly transform to the G(N1-H)[•] tautomer (**27**) with the rate constant of ~2 × 10⁴ s⁻¹.¹⁹⁷ The reducing radicals, identified as the OH adduct at the C8 position of guanine (**30**), are formed with a yield of 17%.¹⁹⁶ These radicals rapidly react with oxygen (*k* ~ 4 × 10⁹ M⁻¹ s⁻¹) and other oxidants such as methylviologen, Fe(III)(CN)₆³⁻, and 1,4-benzoquinone (BQ) to form 8-oxo-7,8-dihydroguanine (**31**) (Figure 10).^{196,208} In the absence of oxygen, the 8-OH-G[•] radicals undergo a rapid ring-opening reaction. A one-electron reduction of the ring-opened product of the 8-OH-G[•] radicals results in the formation of the well-known guanine lesion

2,6-diamino-4-hydroxy-5-formamidopyrimidine (**32**), known as FapyG, as shown in Figure 10.¹⁹⁶

The alternative pathway of [•]OH radical attack is hydrogen-atom abstraction from the 2-deoxyribose moiety, which leads to the formation of the 5',8-cyclo-2'-deoxyguanosine (**33**) lesions.^{209–213} Abstraction of the H atom from C5'H with the formation of the C5'-hydroxymethyl radical (**34**) is followed by intramolecular cyclization via addition of this radical to the C8 position of guanine. The cyclization product is finally oxidized by O₂, thus yielding the 5',8-cyclo-2'-deoxyguanosine lesions (**33**).

3.3.2 Nucleophilic Addition Reactions with Guanine Radicals

As we have already discussed, the products of the one-electron oxidation of guanine bases in DNA are the G^{•+} radical cation and its deprotonated form the neutral G(-H)[•] radical.¹³¹ Both are oxidizing species that do not react with observable rate constants with molecular oxygen.^{56,77,90,92,151} The decay modes of these radical species involve reactions with nucleophiles and combination reactions with other free radicals.^{121,122,214} The nucleophilic addition of water to the G^{•+} radicals cations generates the reducing 8-OH-G[•] radicals (**30**).^{121,122} This radical is also formed by the direct addition of [•]OH radicals to the C8 position of guanine (Figure 10).¹⁹⁶ The one-electron oxidation of 8-OH-G[•] radicals by weak oxidants (O₂, Fe³⁺) generates the widely used biomarker of oxidative stress, the 8-oxoG lesion (**31**). The nucleophilic addition mechanism has been confirmed by the one-electron oxidation of guanine induced by photoexcited riboflavin in H₂¹⁸O solutions.²¹⁵ In agreement with the nucleophilic addition mechanism of water to G^{•+} radicals, the C8-oxygen atom in 8-oxoG was the ¹⁸O-isotope derived from H₂¹⁸O.

Our own experiments have shown that nucleophilic addition reactions of guanine radicals are base-sequence-dependent. When oligonucleotides with the 5'-...GCT... sequence context are (**35**) exposed to one-electron oxidants, a novel intrastrand cross-linked product (**36**) involving a covalent bond between guanine and thymine (Figure 11) was discovered.⁸⁹ This lesion was excised from the oligonucleotide by enzymatic digestion with

Figure 11 Intrastrand G*(C8)–(N3)T* cross-links generated by the one-electron oxidation of guanine in 5'-GCT sequences. [Adapted from Refs 89 and 91.]

nuclease P1 and alkaline phosphatase. The mass and identity of the lesion were identified by liquid chromatography-tandem mass spectrometry (LC-MS/MS) analysis as the dinucleoside d(G^{*}-T^{*}) (37) in which the G(C8) and T(N3) positions are linked covalently. By exposing the dinucleotide 5'-d(GpT) and trinucleotide 5'-d(GpCpT) to carbonate radicals, the same type of 5'-d(G^{*}pT^{*}) and 5'-d(G^{*}pCpT^{*}) lesions were found, respectively. The structures of these species were identified by LC-MS/MS as well as 1D and 2D NMR methods.⁸⁹ The 5'-d(G^{*}pCpT^{*}) cross-linked structure is unusual because G and T are not adjacent to each other in the parent oligonucleotide.

The efficiency of formation of the G^{*}-T^{*} cross-links is base-sequence-dependent⁸⁹ and the greatest efficiency was observed in the case of the 5'-d(GpCpT) sequence. In the case of 5'-d(GpT), the efficiency of formation of the G^{*}-T^{*} product is ~3 times lower. When there are two C bridging residues as in 5'-d(GCCT), the yield of cross-linked products was lower than in the case of 5'-d(GCT). However, no cross-linked products were detected in the case of the 5'-d(GCCCT) sequence which has three bridging C bases. Furthermore, no intrastrand 5-d(T^{*}pC^{*}) cross-links were detected in the case of the dinucleotide 5'-d(TpG) either, although there was a substantial yield in the case of 5'-d(GpT). This latter result supports the conclusion, further supported by experiments with the sequence isomers 5'-d(GpCpT) and 5'-d(TpCpG), that cross-link formation is more efficient when the T residue is on the 3'-side rather than on the 5'-side of the guanine.

Similar cross-links 5'-d(G^{*}pT^{*}) and 5'-d(G^{*}-T^{*}) were also observed in native double-stranded DNA.^{89,90} Since the d(G^{*}pT^{*}) is completely resistant to nuclease P1, we conclude that the product 5'-d(G^{*}pT^{*}) must entirely originate from *intrastrand* cross-linked lesion. However, the same enzymatic digestion of 5'-d(G^{*}pCpT^{*}) leads to loss of pCp, thus yielding the 5'-d(G^{*}-T^{*}) digestion fragment.⁸⁹ Since such an intrastrand G^{*}-T^{*} lesion can arise from any 5'-d(GpN_npT) sequence with N = C or A, and n = 1, 2, 3,⁸⁹ the possibility cannot be excluded that such across-linked lesion can also arise from an *interstrand* cross-linked product.

Thymine is not the only pyrimidine that can form intrastrand cross-links with guanine radicals derived from one-electron transfer reactions. We found that similar cross-links can also be generated

by analogous one-electron oxidation of 5'-r(GpCpU) and 5'-d(GpCpU) trinucleotides containing uracil that lack the C5-methyl group of thymine.⁹¹ Like thymine, uracil contains the N3(H) group that is available for cross-link formation with the C8 site of guanine. The positive ion MS/MS spectra as well as the 1D and 2D NMR spectra of the 5'-r(G^{*}pCpU^{*}) and 5'-d(G^{*}pCpU^{*}) products are completely consistent with G^{*}(C8)-(N3)U^{*} structure, which is entirely analogous to the G^{*}(C8)-(N3)T^{*} cross-links discussed above.

Mechanistically, the formation of G^{*}(C8)-(N3)T^{*} (or G^{*}(C8)-(N3)U^{*}) cross-links includes the loss of two electrons and two protons. While in much of our work CO₃^{•-} radicals were utilized to abstract the first electron from guanine,^{77,90,92,94,150} other one-electron oxidants that have appropriate reduction potentials are equally suitable. Identical cross-linked G^{*}-T^{*} cross-links are formed when SO₄^{•-} radicals and photoexcited riboflavin (a typical type I photosensitizer that reacts with guanine via an electron transfer mechanism) also generate the 5'-G^{*}CT^{*} cross-linked products.^{89,91} Insights into the second electron abstraction step were obtained from our observation that the yields of G^{*}-T^{*} (or G^{*}-U^{*}) cross-linked products are negligible in the absence of molecular oxygen.^{89,91} We rationalized that the second electron is abstracted by O₂, thus forming the superoxide anion O₂^{•-}. This second electron can also be removed by other mild oxidants such as 1,4-benzoquinone in deoxygenated aqueous solutions.⁹¹ Benzoquinone has a redox potential E°(BQ/BQ^{•-}) = 0.078 V versus NHE,²¹⁶ and is a weaker oxidant than O₂ with E°(O₂/O₂^{•-}) = -0.16 V versus NHE.⁷⁸

This mechanism is supported by a strong increase of the yields of the cross-linked product (36) when the pH is increased from neutral to basic values (pH ≥ 10). In a strongly basic solution, T-N3(H) is deprotonated since its pK_a = 9.67,²¹⁷ thus greatly enhancing the nucleophilicity of T-N3. At pH 10, the yield of the G^{*}-T^{*} cross-linked product is ~5 times greater than at pH 7.5, which is fully consistent with the nucleophilic addition of T(N3) to the G(C8) radical. Similar enhancements in cross-linked product yields are also observed in the case of 5'-GCU sequences⁹¹ because T-N3(H) and U-N3(H) have the same pK_a values.²¹⁷ A similar nucleophilic mechanism was proposed by Perrier *et al.* for the formation of cross-linked products between guanine in d(TpGpT) and lysine mediated

by the photoexcited riboflavin in aerated solutions containing the KKK tripeptide.²¹⁸ These authors suggested that an *N* ϵ -(guanine-8-yl)-lysine cross-link is formed via the nucleophilic addition of the ϵ -amino group of the lysine residue to the C8 atom of G^{•+} or G(-H)[•] radicals, followed by the oxidation of the radical adduct formed.

3.3.3 Radical–Guanine Radical Reactions

Guanine radical cations that do not react with any nucleophiles undergo deprotonation to form the guanine radicals G(-H)[•], as already discussed in this article and elsewhere.^{122,219} The combination of guanine neutral radicals with other radicals is one of the most important pathways of the formation of oxidatively generated and stable modifications of guanine. Here, we focus on the combination of G(-H)[•] radicals with oxyl radicals ([•]NO₂, O₂^{•-}, and CO₃^{•-}). These radicals are overproduced at sites of inflammation and are thus of biological significance.^{1–6}

Nitrogen Dioxide Radicals

On the basis of thermodynamic considerations, the direct oxidation of guanine by [•]NO₂ radicals is unfavorable and this was demonstrated experimentally.²¹⁹ Furthermore, G(-H)[•] oxidize NO₂⁻ anions with the rate constant of $\sim 1 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$, which is consistent with the low reactivity of [•]NO₂ with guanine in aqueous solutions.¹⁸⁴ In contrast, [•]NO₂ radicals rapidly combine in bimolecular reactions with G(-H)[•] radicals resulting in the formation of diverse nitration products. We devised two photochemical methods for generating controlled fluxes of G(-H)[•] and [•]NO₂ radicals for studying such radical–radical reactions in detail. The competitive oxidation of NO₂⁻ and HCO₃⁻ anions by photochemically generated SO₄^{•-} radicals (23) to form [•]NO₂ (29) and CO₃^{•-} (24) radicals constitutes the first method.^{87,93} The G(-H)[•] radicals in DNA (derived by the one-electron oxidation of guanines by CO₃^{•-}) rapidly combine with [•]NO₂ radicals to form guanine nitration products. In the second method, the [•]NO₂ radicals are generated by the one-electron reduction of NO₃⁻ anions by hydrated electrons (28) that are produced by the two-photon ionization of 2-aminopurine (39 and 40); in this method, both 2AP and the target

guanine are site-specifically positioned in single- or double-stranded oligonucleotides as described elsewhere in this article.¹⁸⁴ Once the guanine radical G(-H)[•] is formed, it combines with [•]NO₂ radicals on millisecond timescales. This reaction can be directly monitored by transient absorption laser kinetic spectroscopy techniques. The decay of the G(-H)[•] radical absorption band at 315 nm is correlated with the growth of the characteristic absorption band of the nitration products at 385 nm. The combination of the G(-H)[•] and [•]NO₂ radicals is not significantly dependent on the secondary structure of oligonucleotides since the rate constants ($\sim 4.4 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$) are similar in both single- and double-stranded DNA.¹⁸⁴

The same nitrated products are formed regardless of the mode of generation of [•]NO₂.^{87,93,184} These products were isolated by reversed-phase HPLC techniques and unambiguously identified by MS methods. The combination of G(-H)[•] and [•]NO₂ radicals occurs via the addition of [•]NO₂ radicals to either the C8 or the C5 positions of G(-H)[•] radicals (Figure 12). The unpaired electron in [•]NO₂ is delocalized on the N and the O atoms.²²⁰ Therefore, in principle, both the N and the O atoms can participate in reactions with another radical species. In reactions between [•]NO₂ and G(-H)[•] radicals, the covalent bond formed involves the nitrogen atom in the [•]NO₂ precursor molecule. The addition of [•]NO₂ to the C8 position of the G(-H)[•] radical (27) yields the well-known 8-nitroguanine (8-nitroG, 40) adducts, whereas attack at the C5 position generates unstable adducts which rapidly decompose to 5-guanidino-4-nitroimidazole (NIm, 41) (Figure 12).^{87,93} The combined yields of the nitration products NIm and 8-nitroG in aqueous solutions are typically in the range 20–40%. The ratio of the 5-guanidino-4-nitroimidazole and 8-nitroG lesions gradually decreases from 3.4 in the model compound 2',3',5'-tri-*O*-acetylguanosine, to 2.1–2.6 in single-stranded oligonucleotides, and to 0.8–1.1 in oligonucleotide duplexes.

Superoxide radicals are potentially mild three-electron oxidants with the reduction potential $E_7(\text{O}_2^{\bullet-}, 2\text{H}_2\text{O}/4\text{OH}^-) = 1.2 \text{ V}$ versus NHE.²²¹ Owing to their oxidative properties, O₂^{•-} radicals can also contribute to the formation of oxidation end products via radical–radical addition reactions.¹⁰² In order to further explore these radical combination pathways, a photochemical method was developed to simultaneously generate G(-H)[•] radicals in model oligonucleotides and O₂^{•-}.¹⁸³ The

Figure 12 Formation of nitration products via the combination of $\text{G}(-\text{H})^\bullet$ with $\cdot\text{NO}_2$ radicals. [Adapted from Ref. 184.]

hydrated electrons were obtained by the two-photon ionization of 2AP embedded in oligonucleotides as already described (39). The hydrated electrons are quantitatively scavenged by dissolved O_2 to form $\text{O}_2^{\bullet-}$ radicals (31).⁹⁹ The combination of $\text{G}(-\text{H})^\bullet$ and $\text{O}_2^{\bullet-}$ radicals occurs with the identical rate constant $\sim 4.7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ in single- and double-stranded oligonucleotides.¹⁸³ In the presence of $\sim 5 \mu\text{M}$ Cu,Zn-superoxide dismutase (Cu,Zn-SOD, an enzyme that reacts with $\text{O}_2^{\bullet-}$ radicals with nearly diffusion-controlled rates^{18,19}), the lifetimes of the DNA-bound $\text{G}(-\text{H})^\bullet$ radicals are dramatically enhanced from 4–7 ms to 0.2–0.6 s.¹⁸³ This remarkable increase in the lifetimes of $\text{G}(-\text{H})^\bullet$ lifetimes in the presence of Cu,Zn-SOD strongly suggests that the primary partner of reaction of $\text{G}(-\text{H})^\bullet$ radicals in aqueous solutions is indeed the superoxide anion under the conditions described.

The reaction of $\text{G}(-\text{H})^\bullet$ with $\text{O}_2^{\bullet-}$ radicals can produce two different outcomes: (i) electron transfer from $\text{O}_2^{\bullet-}$ to $\text{G}(-\text{H})^\bullet$, which regenerates the guanine and is therefore a “repair” reaction and (ii) formation of oxidatively generated end products.¹⁸³ A detailed analysis by combined HPLC and MS methods showed that these products, in both single- and double-stranded DNA, include mostly 2,5-diamino-4*H*-imidazolone (Iz) lesions and minor amounts of 8-oxoG (Figure 13). The addition of $\text{O}_2^{\bullet-}$ to the C5 position of $\text{G}(-\text{H})^\bullet$ is followed by a rapid protonation of the adduct and the generation of the 5-HOO-G(-H) hydroperoxide (42). This intermediate is unstable and cleaves via the opening of the pyrimidine ring at the C5–C6 bond,

thus generating another unstable intermediate (43) which is readily hydrated at the 7,8-C=N double bond. Ring-chain tautomerization of the carbino-lamine (44) results in the opening of the imidazole ring and a subsequent intramolecular cyclization of the guanidine residue, finally yielding the Iz lesions (45). The latter slowly hydrolyzes to form 2,2-diamino-4-amino-2,5-dihydrooxazol-5-one, Oz (46). Heavy molecular oxygen ^{18}O -labeling experiments showed that the oxygen atom in the Iz lesion originates from $^{18}\text{O}_2$.²²² In the presence of even small quantities of 1,4-benzoquinone ($\sim 100 \mu\text{M}$), the yields of Iz lesions are negligible because BQ reacts with $\text{O}_2^{\bullet-}$ and $\text{G}(-\text{H})^\bullet$ radicals. BQ rapidly reacts with $\text{O}_2^{\bullet-}$ (rate constant $9 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$),⁹⁹ and then the $\text{BQ}^{\bullet-}$ radical thus produced ($E^\circ = 0.078 \text{ V}$ vs NHE²¹⁶) rapidly reduces the $\text{G}(-\text{H})^\bullet$ radical ($E_7 = 1.29 \text{ V}$ vs NHE¹³¹). The addition of $\text{O}_2^{\bullet-}$ to the C5 position of $\text{G}(-\text{H})^\bullet$, followed by the rapid protonation of the adduct, gives rise to the 5-HOO-G(-H) hydroperoxide.^{183,215} The analogous addition of $\text{O}_2^{\bullet-}$ to the C8 position of $\text{G}(-\text{H})^\bullet$, followed by the two-electron reduction of the 8-HOO-G(-H) hydroperoxide formed, leads to the formation of 8-oxoG. The latter is detected in minor quantities, together with the Iz/Oz lesions. This mechanism of 8-oxoG formation has been confirmed by experiments conducted in isotopically substituted water, H_2^{18}O . These experiments reveal that the additional O-atom in 8-oxoG originates from $^{16}\text{O}_2$, which is reduced to $\text{O}_2^{\bullet-}$ by hydrated electrons.¹⁸³

Figure 13 Formation of 8-oxoG and Iz lesions via the combination of G(-H)[•] radicals with O₂^{•-} in DNA. [Adapted from Ref. 183.]

Peroxyl Radicals

In contrast to HO₂[•]/O₂^{•-} radicals, the ROO[•] radicals ($E_7 = 1.0 - 1.1$ V vs NHE) derived from lipid peroxidation exhibit only oxidizing properties.¹⁰² The reduction potential of these radicals^{223,224} is lower than the reduction potential of G(-H)[•] radicals,¹³¹ $E_7 = 1.29$ V versus NHE. Therefore, the thermodynamics of oxidation of guanine by ROO[•] radicals is unfavorable. It is also unlikely that H-atom abstraction from G residues by ROO[•] radicals can occur with observable rates because the bond dissociation energy (BDE) of the C-H bonds in guanine (94.3 ± 0.5 kcal mol⁻¹)²²⁵ is higher than that of the ROO-H bond (~ 88 kcal mol⁻¹, regardless of the exact structure of R²²⁶). However, we have shown that the major pathway of reaction of ROO[•] radicals are their combination reactions with G(-H)[•] radicals.²²⁷ The peroxy radicals were generated by the addition of O₂ to C-centered radicals of polyunsaturated fatty acids, such as arachidonic acid (ArAc),²²⁷ or photolysis of the water-soluble radical generator 2,2'-azobis(2-amidinopropane) dihydrochloride (AAPH).²²⁸ Transient absorbance spectroscopy experiments showed that the alkyl peroxy radicals generated by both methods are unstable and spontaneously decompose to form O₂^{•-} radicals. The formation of O₂^{•-} radicals was directly monitored by the reduction of tetranitromethane.^{99,102} The major products detected in these experiments were

imidazolone formed by the combination reactions of G(-H)[•] radicals with O₂^{•-} and ROO[•] radicals.^{227,228}

The relative contributions of these pathways to the observed formation of the end products were estimated using selective traps of O₂^{•-} radicals, such as 1,4-benzoquinone and Cu,Zn SOD. According to our previous results, BQ and Cu,Zn-SOD completely suppress the formation of the Iz lesions arising from the combination the O₂^{•-} and G(-H)[•] radicals.¹⁸³ The results of these experiments indicate that the formation of Iz occurs by the both pathways (combination of G(-H)[•] radicals with O₂^{•-} and with ROO[•] radicals).^{227,228}

Carbonate Radical Anions

The expected product of bimolecular reaction of the G(-H)[•] radical with strong one-electron oxidants such as the CO₃^{•-} radical is 8-oxoG, the product of a two-electron oxidation of guanine.⁵⁶ However, 8-oxoG is more easily oxidizable by one-electron oxidants than the parent guanine.¹³² The major products of 8-oxoG oxidation are the diastereomeric spiroiminodihydantoin Sp (**50**) and guanidinohydantoin Gh (**51**) products (Figure 14).^{88,90,92,229-234} Our experiments have indeed demonstrated that oxidation of guanine in oligonucleotides to Sp/Gh involves 8-oxoG as an intermediate.⁹² However, when CO₃^{•-} radicals are used as oxidants, the maximum observed yield of 8-oxoG in oligonucleotides does not exceed $\sim 2\%$.

Figure 14 8-Oxoguanine radicals generated by one-electron oxidation or by the addition of hydroxyl radicals. [Adapted from Refs 132 and 236.]

The low yield of 8-oxoG indicates that the rate of oxidation of 8-oxoG is much faster than that of parent guanine embedded in the oligonucleotide. The rate constant of oxidation of 8-oxoG by $\text{CO}_3^{\cdot-}$ radicals is ~ 13 times greater than the analogous rate constant for the one-electron oxidation of guanine in oligonucleotides.⁹² Another factor that decreases the transient yields of 8-oxoG lesions in aqueous solutions of oligonucleotides is that they are rapidly oxidized by $\text{G}(-\text{H})^\bullet$ radicals even though the latter are also embedded in oligonucleotides. Steenken has shown that, at the nucleoside level, $\text{dG}(-\text{H})^\bullet$ radicals oxidize 8-oxodG with the relatively large rate constant of $4.6 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$.¹³² This reaction leads to the recovery of the parent dG and constitutes a very efficient protection of dG against oxidation in nucleoside solutions²³⁵; this accounts for the low levels of 8-oxodG (less than 0.1% of the dG degraded) in oxidation reactions of dG photosensitized by the photexcitation of riboflavin.²³⁵ In double-stranded DNA, on the other hand, the repair of $\text{G}(-\text{H})^\bullet$ radicals by this bimolecular pathway is much less efficient. We have shown that the bimolecular rate constant of oxidation ($2.7 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$) of 8-oxoG in a particular oligonucleotide duplex by a $\text{G}(-\text{H})^\bullet$ radical in another duplex is two orders of magnitude smaller than in the case of free nucleosides.¹⁸³ The

8-oxoG lesion in oligonucleotides is also likely to be an intermediate in the oxidation of the parent guanine bases by $\text{CO}_3^{\cdot-}$ radicals to either Sp or Gh lesions.

3.3.4 Radical Forms of 8-Oxo-7,8-dihydroguanine

The primary product of the one-electron oxidation of 8-oxoG is the radical cation 8-oxoG^{•+} (47) (Figure 14), which can be detected by direct spectroscopic methods by the appearance of the sharp absorption band at 325 nm and a broad, less intense band near 380 nm.^{132,237} In neutral aqueous solutions, the radical cation ($\text{p}K_a = 6.6$) is in equilibrium with its neutral form 8-oxoG(-H)[•] (48), which has very similar spectroscopic characteristics. Recently, O'Neill and coworkers reported that $\cdot\text{OH}$ radicals react with 8-oxodG via the addition to the C4 position and H-atom abstraction from the exocyclic NH_2 group to form highly unstable radicals.²³⁶ The latter rapidly transform to neutral 8-oxoG(-H)[•] radicals within $\leq 1.6 \mu\text{s}$. Our laser flash photolysis experiments^{184,185,237} and the pulse radiolysis experiments of the O'Neill group²³⁶ have shown that 8-oxoG^{•+}/8-oxoG(-H)[•] radicals do

not react with observable rates with molecular oxygen O_2 , and their lifetimes are controlled by other radicals and nucleophiles that may be present,^{184,185,237} as discussed below.

3.3.5 Nucleophilic Addition Reactions with 8-oxoG Radicals

The hydration of the 8-oxoG^{•+} radicals (**47**), followed by a one-electron oxidation of the hydration product, gives rise to the 5-HO-8-oxoG intermediate (**49**). The latter is a precursor of Sp (**50**) and Gh (**51**) that are formed by subsequent oxidation reactions (Figure 14).^{229,238} This mechanism was established by detailed investigations of the oxidation of guanine by the irridium complex $IrCl_6^{2-}$ in $H_2^{18}O$ solutions.²²⁹ Consistent with the nucleophilic addition mechanism, the additional oxygen atom in Sp was found to be the ^{18}O isotope. The transformation of 5-HO-8-oxoG (**49**) to form either Sp (**50**) or Gh (**51**) is pH-dependent. Tannenbaum *et al.* proposed that the partitioning of the two 5-HO-8-oxoG(-H) reaction pathways that lead to the formation of either Sp or Gh is governed by the different reactivities of the deprotonated and protonated forms of this hydrated intermediate ($pK_a \sim 5.8$).²³³ At pH below 5.8 it favors pyrimidine ring-opening, followed by the formation of the Gh lesions, while the acyl shift leading to the Sp lesions dominates at pH > 5.8. This conclusion is in accordance with the higher yields of Gh products at low pH which has been reported for the oxidation of 8-oxoG by peroxynitrite,²³³ by photosensitized riboflavin, and by $IrCl_6^{2-}$ ^{232,239} or Cr(VI) complexes.²⁴⁰

3.3.6 Radical Addition to 8-oxoG Radicals

The neutral 8-oxoG(-H)[•] radical is a key intermediate in the subsequent oxidative cascade of reactions which leads to a variety of stable end products, and its reactions with other radical species defines the nature of the end products formed. In this section, we focus on the combination of 8-oxoG(-H)[•] radicals with oxyl radicals ($\cdot NO_2$, $O_2^{\cdot-}$, and $CO_3^{\cdot-}$), all of which are overproduced at sites of inflammation by macrophages.^{1-3,5,6}

Nitrogen Dioxide

The oxidation of 8-oxodG ($E_7 = 0.74 - 0.79$ V vs NHE)^{132,236} by $\cdot NO_2$ radicals ($E^0 = 1.04$ V vs NHE)⁷⁸ is thermodynamically feasible and occurs with a rate constant of $5.3 \times 10^6 M^{-1} s^{-1}$.²⁴¹ The combination of the 8-oxoG(-H)[•] and $\cdot NO_2$ radicals occurs with similar rate constants ($\sim 4.3 \times 10^8 M^{-1} s^{-1}$) in both single- and double-stranded DNA as shown in our laser flash photolysis experiments.¹⁸⁴ The dominant reaction products are the diastereomeric Sp lesions (Figure 15). The reaction of 8-oxoG(-H)[•] radicals with $\cdot NO_2$ radicals can yield the unstable C5 nitro (**52**) or nitrosooxy adducts. The hydrolysis of these adducts can occur via a nucleophilic addition of a water molecule to C5, followed by the release of the NO_2^- anion and the formation of the 5-HO-8-oxoG(-H) intermediate (**49**), a precursor of the Sp lesions (Figure 15). The 5-HO-8-oxoG(-H) adduct, and hence the Sp end products, contain an oxygen atom derived from $H_2^{18}O$ rather than from $N^{16}O_2$. As described above, the subsequent transformation of 5-HO-8-oxoG(-H) to either Sp or Gh depends on the pH.^{90,229,233,239,240} The mechanism proposed in Figure 15 is consistent with the two basic observations: (i) the combination

Figure 15 Formation of oxidation products via the combination of 8-oxoG(-H)[•] with $\cdot NO_2$ radicals. [Adapted from Ref. 184.]

of $\cdot\text{NO}_2$ and 8-oxoG(-H) $\cdot$ radicals occurs with a rate characteristic of bimolecular radical–radical addition reactions and (ii) the additional O atom in the final oxidation product is derived from H_2O . An alternative proposed reaction mechanism is the one-electron transfer reaction from 8-oxoG(-H) $\cdot$ to $\cdot\text{NO}_2$ which yields the 8-oxoG(-H) $^+$ cation and the NO_2^- anion. In this pathway, proposed by Burrows *et al.* based on their studies of the oxidation of 8-oxoG by IrCl_6^{4-} , the addition of H_2^{18}O to 8-oxoG(-H) $^+$ leads to the 5-HO-8-oxoG(-H) precursor of the Gh and Sp lesions that contain the ^{18}O -isotope which originates from water molecules, as expected.^{229,242} However, the electron transfer mechanism cannot explain the high rate constants for the combination reaction measured by us experimentally for both the 8-oxoG(-H) $\cdot$ radicals and the G(-H) $\cdot$ radicals ($\sim 4.3 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$).¹⁸⁴ This conclusion is based on the typically slow electron transfer reactions of $\cdot\text{NO}_2$ radicals which are the result of the small self-exchange rate constant and high internal reorganization energy in the $\cdot\text{NO}_2/\text{NO}_2^-$ system.²⁴³

Superoxide Anion

The combination of $\text{O}_2^{\cdot-}$ with 8-oxoG(-H) $\cdot$ radicals in double- and single-stranded DNA occurs with the rate constant of $(1.0 - 1.3) \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$.¹⁸⁵ The major end products of this reaction are the dehydroguanidinohydantoin (Gh_{ox}) lesions (**53**) derived from the addition of $\text{O}_2^{\cdot-}$ to the C5 position of 8-oxoG(-H) $\cdot$ (**48**) followed by the decomposition of the 5-HOO-8-oxoG(-H) hydroperoxide (**54**) (Figure 16). According to this mechanism, the cleavage of 5-HOO-8-oxoG(-H) occurs via the opening of the pyrimidine ring at the C5–C6 bond

in 5-HOO-8-oxoG(-H), thus leading to an unstable intermediate (**55**), which decomposes readily with the release of CO_2 and the formation of Gh_{ox} (**53**).¹⁸⁵ The Gh_{ox} lesions are unstable and slowly hydrolyze to oxaluric acid (Oa). In the presence of Cu,Zn-SOD, the yields of the Gh_{ox} lesions are negligible. Under these conditions, the 8-oxoG radicals do not exhibit any observable reactivities with O_2 ($k < 10^2 \text{ M}^{-1} \text{ s}^{-1}$) since they have a decay time of several seconds in air-saturated aqueous solutions at ambient temperatures. The major reaction products are the diastereomeric Sp lesions which are derived via the hydration of 8-oxoG(-H) $\cdot$.¹⁸⁵

Carbonate Radical Anion

The mechanistic aspects of the consecutive oxidation of G(-H) $\cdot$ and 8-oxoG(-H) $\cdot$ radicals by $\text{CO}_3^{\cdot-}$ radicals which result in the formation of Sp lesions from the free nucleoside were investigated in detail in H_2^{18}O buffer solutions.^{88,90} In these experiments, we used 2',3',5'-tri-*O*-acetylguanosine and 2',3',5'-tri-*O*-acetyl-8-oxo-7,8-dihydroguanosine as model compounds⁸⁸ and DNA duplexes derived from the self-complementary sequence⁹⁰ 5'-d(AA-CGCGAATTCGCGTT). In the latter experiments, the Sp lesions were enzymatically excised from the oxidized DNA in the form of 5'-d(C[Sp]) dinucleosides. We found that the oxygen atoms in the tri-*O*-acetyl-Sp and 5'-d(C[Sp]) dinucleosides added to either the C5 or C8 positions of the oxidized guanine intermediates originate from the $\text{C}^{16}\text{O}_3^{\cdot-}$ radicals. The oxidation of the 8-oxoG moieties by $\text{CO}_3^{\cdot-}$ radicals generates Sp products that contain a single O atom which originates from the $\text{C}^{16}\text{O}_3^{\cdot-}$ radicals. In contrast, when the reactions are carried out in buffer solutions containing carbonic anhydrase,²⁴⁴ which enhances the isotope exchange

Figure 16 Formation of oxidation products via the combination of 8-oxoG(-H) $\cdot$ with $\text{O}_2^{\cdot-}$ radicals. [Adapted from Ref. 185.]

Figure 17 The O^- transfer mechanism of the combination of $\text{CO}_3^{\bullet-}$ radicals with $\text{G}(-\text{H})^{\bullet}$ and 8-oxo $\text{G}(-\text{H})^{\bullet}$ radicals to form the Sp and Gh lesions. [Adapted from Refs 88 and 90.]

between $\text{HC}^{16}\text{O}_3^-$ and H_2^{18}O , the Sp nucleoside products contain ^{18}O -atoms. It was concluded that the formation of Sp oxidation products involves the consecutive bimolecular combination reactions of $\text{CO}_3^{\bullet-}$ radicals with $\text{G}(-\text{H})^{\bullet}$ and 8-oxo $\text{G}(-\text{H})^{\bullet}$ radicals (Figure 17) involving monoesters (**56** and **57**, respectively) of the carbonic acid (H_2CO_3) as intermediates. Previous classic experiments of Polanyi and Szabo,²⁴⁵ Ingold,²⁴⁶ and their coworkers demonstrated that in the acid–base hydrolysis of esters, the ^{18}O atoms from water are transferred to the acid component and not to the alcohol product. Since the O atoms in Sp originate from the $\text{CO}_3^{\bullet-}$ radicals and not from H_2O (Figure 17), these findings are consistent with the proposed mechanism of ester hydrolysis. The combination reactions of $\text{CO}_3^{\bullet-}$ with $\text{G}(-\text{H})^{\bullet}$ or 8-oxo $\text{G}(-\text{H})^{\bullet}$ radicals can therefore be formally considered as the transfer of O^- from $\text{CO}_3^{\bullet-}$ to these radicals. The O^- transfer mechanism has been proposed earlier for the reactions of $\text{CO}_3^{\bullet-}$ radicals with inorganic radicals such as $\cdot\text{NO}_2$, $\text{SO}_3^{\bullet-}$, and $\cdot\text{NO}$, which results in the formation of CO_2 , NO_3^- , SO_4^{2-} , and NO_2^- anions.^{247,248} In contrast, metal complexes such as IrCl_6^{2-} involve the consecutive abstraction of two electrons from 8-oxoG, followed by the addition of water molecules to the carbocation intermediates;

thus the oxygen atoms in the Sp products originate from water.²²⁹

4 BIOLOGICAL IMPLICATIONS

Among the many guanine lesions described in this article, 8-oxoG is the best known and most widely studied and is also widely used as a biomarker of oxidative stress in cellular and tissue environments. While all the guanine lesions described in this article have been identified and studied *in vitro*, only 8-oxoG and 8-nitroG have been detected in humans till now.¹²⁰ Detailed studies by several groups have shown that the levels of 8-oxoG in normal human cells are in the range 0.3–4.2 per 10^6 molecules of intact G bases.^{249,250} However, because 8-oxoG is efficiently removed by base excision repair enzymes, it is difficult to accurately measure the levels of 8-oxoG in tissues under inflammatory conditions.^{121,122,251} Furthermore, 8-oxoG is easily oxidized to other products, and it is widely suspected that such deeper oxidation products of guanine are also formed in cells. Significant efforts have been made to identify such adducts in biological systems. Sugden *et al.* found that the spiroiminodihydantoin is indeed formed in *Escherichia coli* cells after treatment

with Cr(VI).²⁵² However, in mammalian cells or tissues, the Sp and other deeper oxidation products were not observable and it was concluded that their levels are likely to be less than 1 in 10⁷ DNA bases.²⁵³ Nevertheless, the four-electron oxidation product of guanine, Oz, has been found at a level of 2–6 Oz lesions per 10⁷ molecules of intact G in liver DNA of diabetic and control rats maintained on a diet of high animal fat.²⁵⁴ In the case of 8-nitroG, there is abundant proof that such lesions exist in tissues although they are unstable because they readily depurinate and dissociate from the DNA. The 8-nitroG adducts have been found in biological fluids of patients with various diseases including chronic hepatitis C,^{255,256} intrahepatic cholangiocarcinoma,^{257,258} nasopharyngeal carcinoma,²⁵⁹ malignant fibrous histiocytoma,^{260,261} *Helicobacter pylori* infection,^{262,263} and inflammatory bowel disease.^{264,265} More research should be conducted to determine whether 5-guanidino-4-nitroimidazole lesions exist *in vivo*; *in vitro*, these Nim lesions are formed with nearly the same proportions as 8-nitroG lesions but, unlike 8-nitroG, do not undergo depurination. Formally, 8-oxoG and 8-nitroG are both products of a two-electron oxidation of guanine. The formation of 8-nitroG occurs in two steps: (i) electron abstraction from guanine (the “first hit”), and (ii) combination of [•]NO₂ radicals (the “second hit”). In contrast, the formation of 8-oxoG requires only one electron abstraction step from guanine (a “single hit”) which is followed by hydration and the abstraction of a second electron from the hydrated guanine radical by molecular oxygen. The formation of the intrastrand G[•]–T[•] cross-links involves a similar sequence of events: first, the one-electron oxidation of guanine (“single hit”) is followed by the nucleophilic addition of T-N3 to G-C8 and the abstraction of an electron by O₂ or another electron acceptor. Such a reaction mechanism may also occur *in vivo*, since molecular oxygen is abundant. Since such G[•]–T[•] cross-linked lesions are also formed in native DNA, further research should be directed toward determining whether these lesions are also formed in cellular DNA.

The Sp and Iz lesions, as well as Oz, the product of hydrolysis of Iz, are, overall, products of the four-electron oxidation of guanine. The Iz lesion is formed by only “two hits,” which are the initial one-electron oxidation of guanine, followed by the

combination reaction of guanine radicals with the superoxide radical anion, a three-electron oxidant. The formation of the Sp lesions *in vitro* can occur via the oxidation of 8-oxoG. Since the levels of 8-oxoG in cells are quite low,^{249,250} the further oxidation of 8-oxoG to Sp by oxidants that can also oxidize guanine seems to be unlikely because guanine is more abundant than 8-oxoG by a factor of ~10⁶. However, oxidants that can oxidize only 8-oxoG but not guanine convert the existing 8-oxoG to deeper oxidation products. Under inflammatory conditions, the best candidates for such reactions are the ubiquitous [•]NO₂ and ROO[•] radicals. The search for Sp and guanidinohydantoin lesions *in vivo*, especially in tissues under inflammatory conditions, is a critically important task that might further clarify the pathways of oxidatively generated guanine damage in DNA associated with reactive intermediates that are products of the inflammatory response.

Osaka, Japan*

1 INTRODUCTION

The principal role of DNA is the long-term storage and replication of genetic information of living organisms. In DNA, π -aromatic compounds, that is, purine and pyrimidine bases, form well-ordered stacking structure, by means of π -stacking between the bases and hydrogen bonding with the bases of the complementary DNA strand to form a double helix structure. For the one-dimensional π -stacked aromatic arrays, charge conduction is also expected.¹ Recently, the charge transfer in DNA has attracted substantial attention of scientists, especially in the field of bioscience and nanotechnology.

In the body, DNA is always attacked by various oxidizing and reducing agents that are generated naturally (see **Reactions of Small Reactive Species with DNA**). The oxidative DNA damage may cause mutation, apoptosis, and cancer.^{2,3} The charge transfer in DNA is a key issue to explain the oxidative damage at remote sites in the DNA. On the other hand, the repair of the damaged DNA also takes place in living cells. For example, DNA photolyase enzymes repair T–T cyclobutane dimer lesions in the DNA duplex, which is generated by UV irradiation, by negative electron (excess electron) transfer in DNA from reduced and deprotonated FADH[–].^{4–6} Thus, understanding of the charge transfer in DNA is essential for the study of photoinduced damage or repair of DNA. Charge transfer in DNA is important for biomedical application, including photodynamic

therapy. For these reasons, great achievements in this subject have been realized by various research groups in the field of biochemistry and radiation chemistry.

From the viewpoint of nanotechnology, DNA is expected to take an important role as a nanowire based on the charge transfer in DNA.^{7,8} DNA can be regarded as an artificial copolymer, whose sequence and chain length can be controlled precisely by means of polynucleotide synthesizer and so on. In addition to natural nucleobases, that is, adenine, cytosine, guanine, and thymine (A, C, G, and T, respectively), various artificial nucleobases can be employed as constituents of DNA with the desired functionality. Although the unit length of one nucleotide of DNA is 3.4 Å and width is ~2 nm, polymerization degree reaches several millions, indicating that well-defined tailor-made properties can be obtained using DNA even in the micro- and millimeter domain. These flexibilities in controlling copolymer sequence and polymerization degree are quite rare in other artificial copolymers. Thus, these quite unique characteristics of DNA which are useful for electric wire in nanoscale appeals to various scientists in fields far removed from biology. Furthermore, DNA is quite useful in forming artificial structures in addition to duplex or quadruplex structures.^{9,10} The nanosheet based on the programmed sequences is one example of such artificial structures.^{11–17} This means that DNA can be employed as a scaffold of various chromophore arrays for various functions.^{18–22} These studies are

also attracting various researchers in a wide range of fields.

Charge transfer in DNA is also an important subject for the scientists in the field of physical and theoretical chemistries. Especially it attracts the attention of scientists who are engaged in the study of electron transfer phenomena in various molecular systems. Can the electron transfer mechanism in DNA be described by the theory developed for conventional molecular systems? Is the rate constant of the charge transfer through DNA faster than that through other materials? How about the sequence and structure dependence of the electron transfer rate? Is the charge in the DNA localized or not? These are very basic issues that have been discussed for various materials such as polymers, supramolecules, and so on for years. In this sense, DNA, whose sequence and polymerization degree are fully controllable, is an ideal system to assess the electron transfer theory (see **Electron Transfer in Peptides and Proteins**).

From these points, the electron transfer in DNA attracts wide attention of various researchers. Our research group has also investigated the charge transfer in DNA by means of laser flash photolysis and pulse radiolysis techniques for years. Here, we summarize our understandings of the charge transfer in DNA.

2 OXIDATION AND REDUCTION POTENTIALS OF THE DNA NUCLEOBASES

In order to discuss the oxidation and reduction processes of DNA, information on the oxidation and reduction potentials is essential. In Table 1, these potentials estimated by the electrochemical method are listed.²³ According to the values listed in Table 1, oxidation potentials of purine bases, that is, G and A, are lower than that of pyrimidine bases. On the other hand, the reduction potentials of the pyrimidine bases, T and C, are higher than those of others. Thus, G and A are considered the target of the oxidation process, while T and C are the target of the reduction process.

The oxidation potentials of nucleobases are also affected by the surrounding conditions. One of the most important surrounding conditions is the neighboring nucleobases in the DNA duplex. For example, it was revealed by Saito *et al.*²⁴ that oxidation cleavage at G shows the sequence

Table 1 The oxidation (E_{ox}) and reduction (E_{red}) potentials of nucleobase.

	E_{ox}/V versus NHE	E_{red}/V versus NHE
G	1.47	< -2.74
A	1.94	-2.43
C	2.12	-2.21
T	2.09	-2.12

Source: Reproduced from Ref. 23. © American Chemical Society, 1996.

selectivity, that is, G adjacent to purine bases is more reactive than that next to pyrimidine bases. GG and GGG sequences are more reactive than GA. This effect can be explained by the lower oxidation potentials of GG or GGG than GA, as revealed by computational study, which estimated that formation of GG or GGG lowers the ionization potential by 0.23 or 0.47 eV, respectively.²⁵ Actual oxidation potential difference between G and GG or GGG was evaluated to be 0.052 or 0.077 eV, respectively, from the evaluation of equilibrium of the hole as discussed in the following section.

In addition to the base stacking, the nucleobase for base pairing has also been revealed to have an effect on the oxidation potentials of the nucleobase. Our research group revealed experimentally that the oxidation potential of 8-oxo-7,8-dihydroguanine (8-oxo-G) is changed by the partner of base pairing.^{26,27} For example, the oxidation potential of 8-oxo-G : 5-methylcytosine is lower than that of 8-oxo-G : C pair by 0.09 V, while 8-oxo-G : 5-bromocytosine is higher by 0.034 V. We confirmed that the difference in the oxidation potentials affected the rate constant of the photoinduced electron transfer with solute in solution.

As summarized in this section, G and A are the targets of the oxidation process, while T and C are targets of the reduction process. That is, the radical cation of G and A or radical anion of T and C will act as the positive or negative charge carrier, respectively. Other important information is that the oxidation and reduction potentials of nucleobases are affected by various factors. The charge transfer in DNA should reflect the difference in the oxidation and reduction potentials, which is affected by surrounding conditions such as neighboring and pairing nucleobases. These factors should become important for fine-tuning of the charge conductivity in DNA. In addition, these issues are quite interesting from the viewpoint of the charge delocalization or localization in DNA. It

should be noted that the stability of the oxidized or reduced nucleobases is also an important factor. For example, it was revealed that reduced C forms the protonated form very rapidly, which decreases its mobility in DNA, as discussed in the following section. Actual hole and excess electron transfers are summarized in the following sections.

3 HOLE TRANSFER IN DNA

Whether DNA is an electric conductor has been an interesting scientific subject from the 1960s.¹ On the basis of the analogy to various organic conductors, in which π -conjugated aromatics form the stacked structure, DNA has been expected to be a good electric conductor owing to its base-stacking structure in the duplex form. The earliest studies on this subject measuring electric current flow in bulk DNA films led to confusing results ranging from conductive to insulating trends.¹ Recent single molecular-level measurements of current flow in the DNA still remain confusing.^{7,8,28}

For the charge transfer in DNA, two kinds of charged species have to be considered in the transport mechanisms. One is the hole transfer in DNA, which is the consecutive oxidation of nucleobase by the neighboring radical cation of the nucleobase that is generated by the hole injection to DNA. The other is the excess electron transfer, in which the radical anion of the nucleobase causes reduction in the neighboring nucleobase. Among them, the hole conduction in DNA has been investigated in detail in advance because many organic crystallines show good hole conductivity.²⁹ Other important motivation for investigation of the hole transfer in DNA is the oxidation of G, which has the lowest oxidation potential among the four natural nucleobases and has close relation to DNA damage.^{2,3} In this section, mechanistic investigations of the hole injection, that is, the electron transfer from the nucleobase to the photosensitizing electron acceptor, are summarized first. Then, the hole migration in the DNA is summarized.

3.1 Hole Tunneling in DNA

During the initial stage of investigation of the electron transfer in DNA, studies were conducted

using electron donors and acceptors, which can be intercalated to DNA in a random manner. Using such systems, Barton and coworkers indicated the fast electron transfer between Ru and Co complexes in the presence of DNA.^{30,31}

In 1992, Harriman and Brun have reported the results of fluorescence lifetime measurements of calf thymus DNA intercalated with ethidium bromide (EB^+) and *N,N'*-dimethyl-2,7-diazapyrenium dichloride (DAP^{2+} ; Figure 1).³² They found the short fluorescence lifetime components due to the electron transfer between EB^+ and DAP^{2+} . The formation of the products of electron transfer was confirmed by transient absorption spectroscopy. They analyzed the fluorescence decay profiles by three components based on the assumption that they came from the electron transfer between EB^+ and DAP^{2+} separated by 3–5 base pairs. According to the Fermi golden rule for the electron transfer, the electron transfer rate is proportional to the square of the electron interaction between the orbitals of the donor and acceptor. Thus, the electron transfer rate (k_{et}) can be expressed as follows using the distance for the electron transfer (r):

$$k_{\text{et}} \propto \exp[-\beta(r - r_0)] \quad (1)$$

where β and r_0 are the dumping factor and contact distance, respectively. The β value has been employed as a characteristic parameter of various conduction media. $\beta = 0$ indicates super conductivity. They evaluated the β value to be $0.88 \text{ \AA}^{-1}$, close to that estimated for proteins.

For a detailed analysis of the distance dependence of the electron transfer, site-selective intercalation of the donor and acceptor is essential. In 1993, Barton and coworkers investigated the electron transfer in DNA by means of the fluorescence quenching experiments. In their system, bis(phenanthroline)(dipyridophenazine)ruthenium(II) ($\text{Ru}(\text{phen}')_2\text{dppz}^{2+}$) and bis(9,10-phenanthrene diimine)(phenanthroline)rhodium(III) ($\text{Rh}(\text{phi})_2\text{phen}^{3+}$), which were tethered to 5' termini of the complementary 15 base pairs, were used as the donor and acceptor, respectively (Figure 2).³³ These metal complexes were intercalated either one or two base steps from the termini of 15 base pair DNA due to high affinity for intercalation, $\geq 10^6 \text{ M}^{-1}$, and intercalation was confirmed by the NMR measurements as well as modeling and product analysis of the photoirradiation. The driving force for the electron transfer was

Figure 1 Electron transfer between intercalators through DNA. [Reproduced from Ref. 32. © American Chemical Society, 1992.]

Figure 2 DNA with Ru and Rh complexes as the donor and acceptor, respectively, investigated by Barton and coworkers. [Reproduced with permission from Ref. 33. © American Association for the Advancement of Science, 1993.]

estimated to be 0.75 eV. Complete fluorescence quenching was observed in the DNA containing both donor and acceptor. The fluorescence lifetime was shorter than their instrumental limitation (300 ps). From these findings, they concluded that the photoinduced electron transfer between intercalated donor and acceptor occurred very rapidly over 40 Å through the DNA helix over pathway consisting of π -stacked base pairs. They confirmed the importance of the intercalation of donor and acceptor in the electron transfer using DNA octamer tethered with $\text{Ru}(\text{phen})_3^{2+}$ and $\text{Rh}(\text{phen})_3^{3+}$, which have lower ability of intercalation, from the no fluorescence quenching. From the estimated lower limit of k_{et} value, they indicated that the β value of DNA as the electron transfer media is lower than 0.2 Å^{-1} . These results attract quite large attentions of the researchers in wide fields.

The long-range hole transfer has attracted attention in relation to DNA damage at a site remote from the hole injections. In 1996, Barton and coworkers reported the oxidative DNA damage caused by hole transfer from the photoexcited Rh complex intercalated to DNA.^{34,35} In the DNA, two GG doublet sites were included at a distance of 17 and 34 Å from the Rh complex as hole acceptor. DNA damage was observed at both sites. The intensity of the oxidative damage at the site distal to the Rh complex is comparable to (or even higher than) that of proximal GG doublet, suggesting that the yield of the damage is not strongly distance dependent.

The electron transfer between the intercalated donor and G was also investigated by Tanaka and coworkers by means of the fluorescence quenching and lifetime measurement.^{36,37} They used methoxy acridine connected covalently to DNA helix as the donor. From the distance dependence, they estimated the β value to be 1.49 Å^{-1} .

The property of DNA as the media for the electron transfer was further investigated by the research groups of Lewis and Wasielewski using the transient absorption spectroscopy. They employed DNA hairpins, in which stilbene dicarboxamide (SA), the electron acceptor, forms a bridge connecting two oligonucleotide arms (Figure 3).³⁸ By selective excitation of SA with the femtosecond laser pulse, they observed the transient absorption band of the SA radical anion with the decay of the singlet excited state, when the G and SA were separated by small number of A (<3). These findings indicate the electron transfer from G to

singlet excited SA, that is, the hole injection. In this system, A separating G and SA did not act as the electron donor for the photoexcited SA. These can be rationalized by the fact that the driving force for the charge separation between G and SA was estimated to be -0.20 eV , while that for A and SA is $+0.25 \text{ eV}$. From the estimated rate constant and the distance for the electron transfer, they evaluated the β value to be 0.64 Å^{-1} , which is larger than the value estimated by Barton and coworkers indicated earlier. For the charge recombination process generating the ground state, they reported a β value of $\sim 0.9 \text{ Å}^{-1}$. The estimated β values of DNA are larger than that of π -conjugated oligomers such as phenylene vinylene in donor-spacer-acceptor system ($\beta < 0.1 \text{ Å}^{-1}$), but smaller than those of proteins (see **Electron Transfer in Peptides and Proteins**) with the rigid hydrocarbon framework ($\beta = 1.0\text{--}1.4 \text{ Å}^{-1}$). Thus, the β value of DNA indicates relative weak electronic interaction between the stacked π -conjugated molecules.

According to the Marcus theory, the k_{et} can be described as a function of the driving force for the electron transfer (ΔG) as follows:^{39–41}

$$k_{\text{et}} = \frac{2\pi}{\hbar} \frac{H_{\text{DA}}^2}{\sqrt{4\pi\lambda_S k_B T}} e^{-S_C} \sum_{n=0}^{\infty} \frac{S_C^n}{n!} \times \exp\left(-\frac{(\lambda_S + \Delta G + n\hbar\langle\omega\rangle)^2}{4\lambda_S k_B T}\right) \quad (2)$$

$$S_C = \frac{\lambda_v}{\hbar\langle\omega\rangle} \quad (3)$$

In (2), λ_S is the solvent reorganization energy, H_{DA} is the electronic coupling, S_C is the electron-vibration coupling constant given by (3), and $\langle\omega\rangle$ is the averaged angular frequency. In (3), λ_v is the internal reorganization energy. The driving force for charge separation from the excited state (ΔG_{CS}) and recombination to the ground state (ΔG_{CR}) can be given by the following Weller's equations⁴²:

$$\Delta G_{\text{CS}} = E_{\text{ox}} - E_{\text{red}} - E_S + C \quad (4)$$

$$\Delta G_{\text{CR}} = E_{\text{red}} - E_{\text{ox}} - C \quad (5)$$

where E_{ox} , E_{red} , E_S , and C are the oxidation potential of the donor, reduction potential of the acceptor, singlet-excited state energy, and Coulombic

Figure 3 DNA hairpins with stilbene dicarboxamide at the loop position as the photosensitizing electron acceptor. [Reproduced with permission from Ref. 38. © American Association for the Advancement of Science, 1997.]

term, respectively. The C term is negligibly small for a polar solvent. The research groups of Lewis and Wasielewski estimated the rate constant of the charge separation (k_{CS}) and recombination (k_{CR}) between the nucleobase, which acts as the electron donor, and electron acceptor at the loop position of the DNA hairpins, and investigated free energy dependence of the electron transfer rate (Figure 4).⁴³ They confirmed that the electron transfer rate can be described in accordance with (2). When the nucleobase, which acts as the electron donor, contacts the electron acceptor, the ΔG dependence of k_{CS} values can be fitted using (2) with λ_S , λ_V , and H_{AD} values being 0.31 eV, 0.61 eV, and 230 cm^{-1} , respectively. They pointed out that these values are similar to those reported for the cyclophane-bridged donor–acceptor molecules and that the relative small H_{DA} value supported the electron transfer in the nonadiabatic region, which is a prerequisite of the treatment with (2). They also estimated the k_{CS} and k_{CR} values of DNA hairpins, in which the electron acceptor and the nucleobase, which acts as

the electron donor, are separated by two A-T pairs. The λ_S , λ_V , and H_{DA} values were estimated to be 0.41 eV, 0.60 eV, and 17 cm^{-1} , respectively. The λ_S and λ_V values did not show substantial distance dependence. The smaller H_{DA} value of the latter system reflects exponential dependence on the donor–acceptor distance as follows:

$$H_{DA} = H_{DA}^0 \exp[-\beta(r - r_0)/2] \quad (6)$$

From this relation, they estimated the H_{DA}^0 value to be 400 cm^{-1} . These findings indicate that the single-step electron transfer in DNA mediated by nucleobases can be described by Marcus theory developed for nonadiabatic electron transfer systems.^{39–41}

In this section, the hole injection process in DNA is summarized. In the electron injection process to DNA, G, which possesses the lowest oxidation potential among the four natural nucleobases, acts as the electron donor against the photosensitizing electron acceptor. The hole injection process has

Figure 4 Free energy dependence of the charge separation and recombination rates. I and II are the electron transfers between the photosensitizing electron acceptor and neighboring nucleobase. III and IV are electron transfer between the electron acceptor and nucleobase separated by two A–T pairs. I and III are determined for the charge separation processes. II and IV are for both charge separation and recombination. [Reproduced from Ref. 43. © American Chemical Society, 2000.]

been successfully described by the Marcus theory (2), the electron transfer theory for the nonadiabatic region, in which the electronic interaction between the donor and acceptor is small or moderate. The forward and backward electron transfer rates showed clear parabola-like dependence against the driving force for the electron transfer. Furthermore, the electron transfer rates decreased exponentially with the distance as expected from (1) and (2), supporting that this is the electron tunneling process, governed by the superexchange interaction. As the β value of the DNA, $\beta = \sim 0.7 \text{ \AA}^{-1}$ seems to be accepted widely, although the reported values showed some scattering at the initial stage of this study. This value is located between the conjugated polymer and hydrocarbons including proteins. In this sense, this value is reasonable for the stacked aromatic compounds.

3.2 Hole Hopping in DNA

In the process of hole injection to DNA, which was described in the previous section, the driving force for the electron transfer is exothermicity. Thus, the hole injection rate is on the order of picoseconds in some cases. Once a hole is injected, it can migrate in DNA by successive oxidation of the neighboring nucleobase by nucleobase radical

cation. This process can be categorized as a multistep hole hopping process. In the hole hopping, the driving force for electron transfer between the same kind of nucleobases is zero. Thus, a nanosecond to microsecond timescale is expected for the hopping rate.

In the case of the hole hopping process, G radical cation is expected to act as an important charge mediator, because G has the lowest oxidation potential among the four natural nucleobases, as indicated in the earlier section. That is, oxidation of nucleobases by G radical cation is an endothermic process. Giese and coworkers have investigated the oxidation of GGG by hole transfer from G radical cation separated by A:T pairs by product analysis using gel electrophoresis.⁴⁴ When the number of A:T pairs is less than 5, they confirmed that the formation of GGG radical cation decreased as an exponential function of distance. From the product yield, they have estimated the β value to be $0.7 \text{ \AA}^{-1}$, which is the same as that summarized in the earlier section. In addition, they observed quite high yield of GGG radical cation even when the GGG was separated from G radical cation by 15 base pairs (54 Å), in which several Gs were included acting as relay stations or stepping stones for the hole on the way to the GGG unit (Figure 5). Thus, the hole transfer from the initially formed G radical cation to GGG does not occur in one step but in a multistep

Figure 5 Single-step electron transfer and multistep electron transfer. [Reproduced from Ref. 44. © American Chemical Society, 2000.]

manner, that is, G hopping. In this case, charge migrates by a random work because there is no driving force. The efficiency of the charge transport (E) can be expressed as a function of number of steps (N), as follows:

$$\ln E \propto -\ln N. \quad (7)$$

One of the important characteristics of (7) is the smaller distance dependence when compared to (1), supporting the long-range hole migration.

In 2001, Giese and coworkers investigated the hole transfer from G radical cation to GGG unit separated by only A:T pairs without G, which acts as a stepping stone between initially formed G radical cation and GGG.⁴⁵ When the number of A:T pair is less than 3, the yield of the product due to oxidation of GGG decreases by a factor of 8 for each additional A:T pair. Further elongation of the A:T sequence did not change the yield of GGG radical cation (Figure 6). They explained the smaller distance dependence for DNA with longer

A:T sequence as the contribution of hopping of A radical cation formed by oxidation by G radical cation, that is, A hopping.

For the determination of the rate constant for A hopping, our research group investigated the charge separation and recombination processes in DNA hairpin conjugated with naphthaldiimide (NDI) and phenothiazine (PTZ) as the photosensitizing electron acceptor at loop position and hole trap at 5' end, respectively.⁴⁶ The selective excitation of the NDI generated NDI radical anion and PTZ radical cation within the nanosecond laser duration even when the NDI and PTZ were separated by eight A:T pairs, indicating rapid hole migration by A hopping mechanism. By applying (8) to the dependence of the yield of the radical ion pairs (Φ), that is, NDI radical cation and PTZ radical anion, on the number of A:T base pairs, the rate constant for the single hopping rate (k_A in Figure 7) was estimated to be $2 \times 10^{10} \text{ s}^{-1}$:

$$\Phi = (k_2/k_1)/[1 + (N - 1)(k_2/k_1)] \quad (8)$$

where k_1 and k_2 are the rate constants for the charge recombination and hole shift from A to PTZ, respectively. The estimated rate is quite rapid compared to the estimated value for the G to GG or GGG separated by one A.

This fast hopping rate among consecutive A sequences is considered to enable the efficient charge migration even if the photosensitizing donor and hole acceptor are separated by long distance. This was confirmed in 2006.⁴⁷ When naphthalimide (NI) and PTZ were connected by DNA sequence including consecutive 30 A:T pairs, it was observed that the generation of PTZ radical cation due to the hole migration by A hopping completed within the nanosecond laser duration, indicating long-distance hole migration over 100 Å within several tens of nanoseconds. Furthermore, we confirmed that the very weak distance dependence of the yield of PTZ radical cation is in accordance with the fast A hopping rate.

In 2010, the research groups of Lewis and Wasielewski examined the hole migration process in DNA hairpins conjugated with SA and stilbene diether (SD) by means of the femtosecond and nanosecond laser flash photolysis (Figure 8).⁴⁸ They applied (9) for the unbiased first passage random walk in one dimension to generation kinetics of SD

Figure 6 Yield of oxidation product of GGG depending on the number of A–T pairs located between G radical cation and GGG. [Reproduced from Ref. 45. © Nature Publishing Group, 2001.]

Figure 7 Molecular structures of NDI and PTZ conjugated to DNA hairpins at loop and 5' end. Schematic energy diagram of A hopping in DNA hairpins. [Reproduced from Ref. 46. © American Chemical Society, 2004.]

radical cation:

$$\tau(N) = (1/2k_{\text{hop}})N^2 \quad (9)$$

where $\tau(N)$ is the time required for N hopping and k_{hop} is the rate constant for the single hopping step. They evaluated 4.3×10^9 and $1.2 \times 10^9 \text{ s}^{-1}$ for the k_{hop} values of G-to-G and A-to-A hopping rate, respectively. Furthermore, from the temperature dependence, they evaluated the activation energy for the hopping in the diblock DNA hairpin to be $2.8 \text{ kcal mol}^{-1}$ with an A factor of $7 \times 10^9 \text{ s}^{-1}$, consistent with weakly activated, conformational gated process.

Although there is discrepancy in the reported A hopping rates, it is reasonable to say that the consecutive A–A or G–G hopping rates is of smaller than nanosecond order. The several ten or hundred picosecond-order hole hopping rate along the consecutive sequence can be attributed to the shorter distance between the sites to be hopped (i.e., $3.4 \text{ \AA}$ for B-type DNA). But in the case of G hopping through one or more intervening A, C, or T, the hopping rate should be slowed down because the A, C, or T should work as the barrier for the hole hopping.

The actual hole transfer rate from G radical cation to GG or GGG separated by A was obtained

Figure 8 (a) Transient absorption spectra of diblock DNA hairpin conjugated with SD and SA at loop and end cap position. (b) The kinetic trace of SD radical cation during the nanosecond laser flash photolysis. [Reproduced from Ref. 48. © American Chemical Society, 2010.]

from the DNA hairpins, which have SA at the loop position, by the research groups of Lewis and Wasielewski.^{49–51} From the analysis of the kinetic trace of the SA radical anion of the DNA, in which G and GG were separated by single A:T pair, the forward and backward hole transfer rates were estimated to be 5×10^7 and $6 \times 10^6 \text{ s}^{-1}$, respectively. The difference in the forward and backward hole transfer rates reflects the relative energy of the G and GG radical cation. From these values, they estimated that GG radical cation is more stable than G radical cation by 0.052 eV. Thus, it was revealed that the timescale of the single-step hole transfer in DNA is in the order of several ten to hundred nanoseconds order, which is in accordance with the smaller driving force for the electron transfer. Furthermore, they estimated the hole

transfer rate from G to GGG to be 8.7×10^7 and $4.3 \times 10^6 \text{ s}^{-1}$ for forward and backward hole transfers, respectively. In this case, GGG radical cation is lower in energy than that of G by 0.077 eV. These values support the theory that the oxidation potential of G is affected by the surrounding nucleobases as suggested by theoretical calculations and formation of stable radical cation in the consecutive G sequences.

Our research group estimated the hole transfer rates between two Gs separated by A or T by nanosecond laser flash on the DNA conjugated with NI and PTZ (Figure 9).⁵² In this DNA, the hole generated by the photosensitizing electron acceptor, NI, was once trapped by the G by fast hole migration along A consecutive sequence, and then migrated to the PTZ by repeated G-A-G hopping. It was confirmed that the generation rate of PTZ radical cation depends on the number of G-A-G in accordance with one-dimensional random walk model. From the analysis of the kinetic trace of PTZ radical cation, the rate constant for the single hopping was estimated to be $4.8 \times 10^7 \text{ s}^{-1}$. In a similar manner, the single-step G-T-G hopping rate was estimated to be $4.6 \times 10^5 \text{ s}^{-1}$. The two-order smaller hopping rate of G-T-G than that of G-A-G can be attributed to the higher oxidation potential of T, which decreases electronic coupling between two Gs in accordance with the tunneling theory. In addition, the effect of the number of intervening A or T was also examined (Table 2). It was revealed that the insertion of the additional A or T dramatically decreased the hopping rate in an exponential manner, as pointed out by Giese *et al.*

^aInterstrand hole hopping rate.

We also estimated the interstrand G hopping rates using DNA sequences including G-A-C or G-T-C. The estimated rates were almost identical (Table 2) and were slower than that of intrastrand G-A-G due to the longer distance to be hopped.

In the case of hopping between two Gs separated by C, inter- and intrastrand G hopping processes have to be considered, as indicated in Figure 10.⁵³ By applying the model of Figure 10 to kinetic trace of the generation profile of PTZ radical cation, rate constant for the G hopping was estimated to be (3.6–4.0) × 10⁸ and (1.0–1.2) × 10⁸ s⁻¹ for the inter- and intrastrand mechanisms, respectively. The estimated values were faster than that for G-A-G hopping rate, which should be faster than that for G-C-G intrastrand G hopping because of the lower barrier to be hopped. From this reasoning, the observed hole hopping can be attributed to the interstrand G hopping with the rate of (3.6–4.0) × 10⁸ s⁻¹. The estimated value, which is smaller than that reported for consecutive G sequence,

seems to be reasonable, because the distance to be hopped should be larger than that for the consecutive G.

As indicated in this section, the hopping rate between two Gs separated by A, C, or T was lowered because these nucleobases with higher oxidation potential than G act as a barrier for the electronic hopping. Thus, inclusion of barrier decreases the hole migration rate. For the realization of the fast hole migration, one of the possible strategies is the inclusion of the artificial nucleobases that possess a highest occupied molecular orbital (HOMO) level similar to that of G.⁵⁴ To test this idea, our research group employed 7-deazaadenine (Z), in which N7 nitrogen of adenine was substituted with C–H group to have an oxidation potential (1.39 V vs NHE) similar to that of G (1.31 V). It was confirmed that by substituting A:T with Z:T, a three-order enhancement of the charge transfer rate was achieved.

In this section, the hole hopping along G and A, of which oxidation potentials are lower than those of the other two, are summarized. Although the electron tunneling mechanism limits the distance for the hole transfer to 3 or 4 nucleobases, successive hopping, that is, repeated electron tunneling, allows long-distance hole migration. The distance of the hopping can reach up to hundreds of angstroms. The single-step hopping rate is on the order of several ten to hundred picoseconds, when A or G is not separated by other nucleobases. When single A or T is inserted between the two Gs, the hopping rate decreases to 10⁵–10⁷ s⁻¹, that is, several ten to hundred nanoseconds. Further decrease in the rate was observed when the number of the intervening A or T was increased. On the other hand, when single C is inserted between the two Gs, interstrand hole hopping becomes operative. This decrease in the hole hopping rate can be rationalized by the increase in the barrier height for the hole tunneling. In this sense, this phenomenon can also be described by the conventional electron transfer theory.

3.3 Hole Transfer in Various Structures

One of the important and unique characteristics of DNA is the variety of higher order structures depending on the DNA sequence and/or conditions. One such structure is the T:A·T triplex, in which T:A forms normal Watson–Crick duplex and a

third T is associated by Hoogsteen hydrogen bonding. T:A·T triplex has a structure similar to B-DNA duplex with a 3.3-Å stacking distance and 28° helical pitch. The research groups of Lewis and Wasielewski prepared T:A·T triplex with SA- and SD-linked DNA hairpin, in which SA linked T:A, while SD formed a linkage with the third T (Figure 11).⁵⁵ In these DNA hairpins, T:A·T triplex acts as a spacer of electron transfer

to the photoexcited SA from SD. The electron transfer to photoexcited SA was confirmed by formation of SA radical anion with the decay of the singlet-excited SA in the femtosecond transient absorption spectroscopy. From the distance dependence of the electron transfer rate, the authors determined the β value for charge separation to be 0.39 Å^{-1} , which is smaller than that for the duplex (0.64 Å^{-1}), while the β value for the

charge recombination ($1.0 \text{ \AA}^{-1}$) is similar to that of the duplex ($0.94 \text{ \AA}^{-1}$). The authors indicated that the shorter base pair stacking distance of triplex and lower oxidation potential of A in the triplex than that in the duplex lowered the energy gap between electron donor and bridge state. This finding also supported the electron transfer by electron tunneling, mediated by the super exchange interaction.

In the case of the above-mentioned triplex structure, the base pairing is maintained. But in the case of DNA structures such as bulge and loop, base pairing is disrupted, forming a bent structure. In 1997, Barton and coworkers reported the effect of the insertion of three kinds of bulge, that is, A_n , T_n ($n = 1 - 3$), and ATA, between the photosensitizing hole donor and GG hole acceptor (Figure 12).⁵⁶ They found that the insertion of the ATA bulge between the proximal and distal GG doublets diminished the oxidation of distal GG doublet by a factor of 4. They also found that insertion of a single A or T bulge effectively diminishes the oxidation of the distal GG doublet, although the effect increases with the n of A_n or T_n . These results indicate the importance of base pairing in DNA long range hole transfer.

The mismatch of the base pairing is another source of the disruption of the base stacking, which has been shown to affect the charge transfer in DNA. There are several reports that show that the mismatch inhibits the DNA charge transfer.^{57–59} Giese and Wessely demonstrated that a G-containing mismatch decreases the efficiency of the charge transfer.⁵⁷ Barton and coworker demonstrated that

the yield of the long-range oxidative DNA damage through intervening mismatches correlates with the imino proton exchange rates of the mismatch in a millisecond.⁵⁸ Schuster and coworker reported a larger effect of T:T mismatch than A:A.⁵⁹ For the quantitative analysis of the effect of the mismatch on the charge transfer efficiency, the estimation of the rate constant for the charge transfer through the mismatch is essential. From this point of view, we have investigated the charge transfer process through the mismatch.⁶⁰ In Figure 13, DNA sequences investigated in the study are summarized. The 14 assemblies, which possess NI and PTZ as the photosensitizing hole donor and hole acceptor, respectively, can be classified into three groups, that is, assembly 1 (bridge parts; A:T), assembly 2 (T:A), and assembly 3 (AA:TT). The mismatches were introduced into the bridge parts of the complementary base of G or several intervening bases between the two Gs (A:A, T:T, or A:C mismatch). In Table 3, the rate constant for the GG hopping with mismatch sequences are shown. From the rate constants in Table 3, it was indicated that the charge transfer from fully matched G to the G-containing mismatch is slower than that for fully matched assembly, while the charge transfer from the G-containing mismatch to the fully matched G is faster than that for the fully matched one. In addition, the charge transfer across the T:T or A:C mismatches are slower than that for the fully matched assembly, while the charge transfer across A:A mismatch is faster than that for the fully matched one. Since the decrease in the hole transfer rate can be associated with the decrease in the base stacking, we also estimated the melting temperature of the assemblies (Table 3). It was clear that the inclusion of the mismatches decreased melting temperature and one-to-one correlation was not observed. From the estimated rate constants for the charge transfer through the mismatch, we have shown that the kinetic discrimination of mismatch sequence is possible.

As the building block of the nanostructure, DNA has been widely employed. In the construction of the nanostructure by DNA, the sequence called *sticky end*, which ensures the selective base pair formation with other DNA chain, is often employed. We have also examined the effect on the charge transfer of the existence of the sticky ends between the photosensitizing hole donor and acceptor.⁶¹ From the comparison, we have confirmed that the effect

of the sticky end is rather small, in accordance with the electrochemical study carried out by Liu and Barton.⁶²

In addition to the structures indicated in this section, various DNA structures have been reported. For these structures, factors governing the electron transfer, such as base pair distance and flexibility, should be altered. As a result, the charge transfer in these structured materials should be sensitive to the structures. These issues will be important subjects to be clarified.

3.4 Application of Hole Transfer

One of the important motivations for the research on the hole transfer in DNA is the clarification of the relation with the oxidative damage of DNA. The mechanism of the damage of DNA by the photoinduced process has been categorized into two types. One is the oxidation of DNA by the photosensitizer (type I) and the other is the oxidation of DNA mediated by singlet oxygen (type II). Since the reaction rate of G radical cation and water, which causes the DNA damage, is quite slower ($\sim 5 \text{ s}^{-1}$ or slower)^{63,64} compared to the charge recombination rate between the photosensitizer and initially generated radical cation, the long-lived radical cation of DNA, which can be generated by

the long-range hole hopping, should be essential in type I DNA damage. In order to confirm this hypothesis, we compared the DNA damage, which can be quantified by the loss of G after the photolysis, the charge separation yield, and the charge recombination rate.⁶⁵ As a simplified model, in which the reaction of the oxygen and G radical cation determines the amount of DNA damage, the following equation can be derived

$$[\text{DNA damage}] = (\text{constant}) \times \phi \times k_{\text{O}_2}[\text{O}_2]/(k_{\text{O}_2}[\text{O}_2] + 1/\tau) \quad (10)$$

where ϕ and τ are the yield of long-lived charge-separated state and lifetime, respectively. In Figure 14, the loss of G was plotted against the lifetime of the generated radical cation. The values estimated by (10) are indicated by cube and diamond in Figure 14, which are in good accordance with the experimental values. These results indicate that the generated long-lived holes, especially generated by fast hole hopping to have longer lifetimes of ten to hundred microsecond regions, cause DNA damages. In this sense, consecutive A or G sequence, which realizes fast charge transfer after the initial hole injection, will enhance DNA damage.

As indicated in the above section, the rate of hole hopping, which has a close relation with the yield of the final oxidized species, is largely affected by the DNA sequence. Another important application of the estimation of hole hopping in DNA will be the

**Figure 14** The relation between the loss of G and the lifetime of the generated radical cation. [Reproduced from Ref. 65. © Elsevier Inc, 2005.]

read out or detection of the single-base mismatch. In order to realize this issue by optical method, we examined detection with the single molecular fluorescence spectroscopy.⁶⁶ In this system, DNA was conjugated with the photosensitizing electron acceptor and reporter fluorescence molecules at both the ends (Figure 15). The hole migration to the reporter fluorescent molecule quenches the fluorescence, while mismatch in DNA decreases the amount of fluorescence quenching by diminishing the hole transfer to the reporter fluorescent molecule (Figure 15). As indicated in the bottom graph of Figure 15, the photobleaching efficiency decreased when the DNA included the mismatch sequences. Furthermore, the efficiency was also sensitive to the position of mismatch. This will be one of the simple applications of the hole migration in mismatch detection. In addition to the conventional organic dye, we also indicated that titanium dioxide can also be used as the photosensitizing electron acceptor for the detection of the mismatch sequence by employing the single molecule fluorescence spectroscopy system.⁶⁷

In addition to the biomedical application, application to nanoscale electronic wiring is another interesting field. In the construction of the nanostructure by DNA, the sequence called *sticky end*, which ensures the selective base pair formation with other DNA chain, is useful. The employment of such sticky ends seems to be useful in biomedical application also. From this viewpoint, we have examined the hole transfer in DNA composed of several blocks, which were connected by sticky ends (Figure 16).⁵³ In this system, the DNA includes three blocks, that is, charge injection block (red), conductive block (green), and charge detection block (yellow). Three blocks form one duplex by means of the connection at the sticky ends. When the conductive block is the full match sequence, fast generation of PTZ radical cation was confirmed, while the inclusion of the mismatch lowered generation rate drastically. Thus, these block structures will be useful in the construction of nanostructured materials with the conductive functions.

In addition to the higher structure of DNA, which can be generated depending on the sequence and/or

surrounding condition, several artificial structures can be realized by the introduction of functional molecules. The DNA conjugated with perylene bisimides (PDI), as investigated by the research groups of Lewis and Wasielewski, is one of the examples of these artificial DNA.⁶⁸ In this case, because of its hydrophobic interaction, PDI tends

to form a dimer. They have investigated electron transfer process and structural relaxation in the formed aggregates.

In this section, some examples for the application of hole migration in DNA are indicated. Applications in the biomedical field are oriented to the detection of mismatch sequence and photodynamic therapy by the photoinduced reactions. From the viewpoint of nanotechnology, nanoscale wiring using DNA attracts wide attention. These studies will be continued by various research groups.

3.5 Summary for Hole Transfer in DNA

In this section, research on the process of hole transfer in DNA is summarized. The mechanism of hole transfer has been established in detail. When the distance for the single-step electron transfer is shorter, typically shorter than 3 or 4 nucleobases, the electron tunneling mediated by the super exchange interaction is the main mechanism. The electron transfer rate can be reproduced by means of the Marcus theory developed for the nonadiabatic conditions. The electron transfer rates are of subpicosecond levels for the short-range and largely exothermic hole injection process. For the long-distance hole transfer, hopping mechanism, in which each step is governed by the tunneling electron transfer theory, is operative. The hopping mechanism can be analyzed by random walk model and ranged to the longer distance even more than hundreds of angstroms. The rate of each hole transfer has also been estimated. The sub-nanosecond rate constants are estimated for A–A and G–G hopping, while it decreases to microsecond to millisecond region when other nucleobases, which act as barrier for hopping, are inserted between A–A or G–G. This long-range hole transfer has close relation to the DNA damage, which is the result of the reaction of the oxidized G and water or molecular oxygen. Thus, the hole transfer is important to develop new photodynamic therapy. In addition, application to nanotechnology as the molecular wire, whose conduction is sensitive to its sequence, is also promising.

4 EXCESS ELECTRON TRANSFER IN DNA

Compared to the hole transfer in DNA, our understanding of the excess electron transfer in DNA,

in which electron acts as a charge carrier, is not sufficient. In this section, research relating to the excess electron injection and migration will be summarized.

4.1 Excess Electron Tunneling in DNA in Low-Temperature Glass

Sevilla and coworkers reported the ESR study on the excess electron transfer in DNA caused by γ -ray radiolysis.⁶⁹ In their system, DNA including intercalator randomly was irradiated with γ -ray in 77 K glassy matrix. The excess electron generated on DNA nucleobases transfers to the intercalator, such as mitoxantrone (MX), EB⁺, 1,10-phenanthroline, and 5-nitro-1,10-phenanthroline, with the timescale of minutes to weeks, which can be monitored by the ESR signal of the radical anion of the nucleobases. In this system, both excess electron and intercalator are distributed randomly in DNA. The excess electron captured by the intercalator increased logarithmically with time as expected for the single-step electron tunneling from the nucleobase radical anion to the intercalator. The distance for the electron tunneling was estimated to be 4–10 base pairs after 1 min at 77 K. The estimated rate was on the order of 10^0 – 10^1 s⁻¹, from which they estimated the β value of (1) to be 0.85–1.2 Å⁻¹ depending on the intercalator.

In 2000, they reported the effect of temperature on the excess electron transfer in DNA with MX intercalator in D₂O, which was employed to distinguish T radical anion and protonated reduced C.⁷⁰ They found that the excess electron tunneling from DNA to MX is the dominant process at less than or equal to 77 K. The β value was the same at 4 and 77 K. The lack of temperature dependence indicates the absence of the vibronic states in this temperature range. Deuteration of T radical anion at C6 position takes place irreversibly above 130 K, which competes with the electron tunneling and acts as an irreversible sink for the electron. Hybridization of G and C results in the protonation of C radical anion at N3 position in a reversible manner, which stabilizes substantially. They indicated that the hole and electron hopping resulting in the recombination of G radical cation and protonated reduced C becomes substantial over 195 K, while the electron transfer from C radical

anion is too slow to be observed under 170 K, at which hopping is activated.

Furthermore, in 2002, from the ESR measurements on polydAdT·pdAdT and pdIdC·pdIdC intercalated with MX, they estimated the β and ET distance depending on the base sequence.⁷¹ The estimated β and ET distance were 0.75 Å⁻¹ and 9.4 base pairs for polydAdT·pdAdT, respectively, while they were 0.92 Å⁻¹ and 9.5 base pairs for pdIdC·pdIdC. They attributed these results to slow deuteron transfer from I to C radical anion forming CD radical.

From the series of the ESR study on the γ -ray-irradiated DNA with intercalator, Sevilla *et al.* successfully revealed the tunneling behavior of the excess electron in DNA. Especially, the contribution of the protonated radical anion to the excess electron transfer is an important finding, which is obtained by ESR measurement. In addition, application of the radiation chemical method is another advantage in excess electron transfer study because of the high ability of the radiation chemical method in the generation of the reduced form of organic materials. By employing the pulse radiolysis technique, which is another important radiation chemical technique, Kobayashi *et al.* reported the transient absorption spectrum of the reduced nucleobases, which showed the delocalization of the excess electron over several nucleobases.⁷² On the other hand, oxidation and reduction by radiation chemical method occurs in a random manner. In addition, oxidation or reduction of the target molecules occurs by a reaction with initially generated oxidized or reduced solvent species. This reaction mechanism limits the time resolution of the kinetic research. The difficulty in the site-selective oxidation or reduction and time resolution limits the detailed investigation of the charge transfer in DNA by radiation chemical method. Although our research group also applied pulse radiolysis for determination of the rate constant of the excess electron transfer in DNA, the actual rate was not obtained because of these limitations.⁷³

4.2 Excess Electron Hopping in DNA

In 2002, Carell and coworkers investigated the distance dependence of the excess electron transfer in a DNA conjugated with the reduced flavin

Figure 17 DNA conjugated with the reduced flavin and thymine dimer as the electron donor to DNA and acceptor, respectively. [Reproduced with permission from Ref. 74. © Wiley-VCH Verlag GmbH & Co. KGaA, 2002.]

and T dimer as the electron donor and acceptor, respectively (Figure 17).⁷⁴ It was indicated that the UV irradiation to consecutive T sequence generates cyclobutane pyrimidine dimer lesions in DNA, which can be repaired by DNA photolyase enzymes by the electron transfer from reduced and deprotonated FADH^- cofactor to cyclobutane dimer. In this sense, this system mimics such DNA repair systems. In their system, T dimer and flavin were separated by A:T base pairs (Figure 17). Photoirradiation to reduced and deprotonated flavin causes the excess electron injection to T in the vicinity of flavin. The excess electron transfer to T dimer causes the cycloreversion of a T dimer, which can be detected by HPLC. From the yield of the cycloreversion of T dimer depending on the number of the intervening A:T pairs, they estimated the distance dependence of the electron transfer yield. By employing (1), they estimated the β value to be $0.11 \text{ \AA}^{-1}$. They attributed this small β value to hopping mechanism. Actually from a plot according to (7), the slope was estimated to be ~ 2 , which is in accordance with the one-dimensional random walk model. Using this system, they confirmed that the excess electron induced to DNA can migrate to over $24 \text{ \AA}$. They also fabricated DNA hairpins with flavin

and T dimer as the donor and acceptor, respectively, and found a similar distance dependence of the excess electron transfer.^{75–77}

In addition, using this flavin donor and T dimer acceptor, they investigated the excess electron transfer in PNA:DNA hybrid.⁷⁸ In this hybrid system, flavin donor and T dimer acceptor were included in PNA and DNA chains, respectively. They found that the yield and distance dependence were similar to those of the DNA duplex system, indicating efficient interstrand excess electron transfer. Furthermore, their PNA:DNA hybrids did not show the directional preference of the excess electron migration (i.e., $5' \rightarrow 3'$ or $3' \rightarrow 5'$).⁷⁹ Since the split rate of the T dimer is in the order of 10^6 s^{-1} , they suggested that the rate-determining step of this dimer cleavage may be the splitting rather than the excess electron transfer in DNA, indicating the fast electron transfer in DNA. This issue was examined by them in 2006. They employed BrU, BrA, and BrG as the electron acceptor of the excess electron transfer in DNA, while flavin donor was also employed in this system.⁸⁰ They investigated the effect of G:C pair insertion in A:T pairs on the excess electron transfer yield. It was revealed that the DNA with the electron acceptor with higher electron accepting ability

(BrU) is sensitive to the insertion of G:C pair, because the higher electron accepting ability of BrU makes the electron trapping faster than the excess electron migration in DNA. From these results, they indicated the importance of the electron acceptor, to which the electron trapping is fast enough, in the investigation of the electron migration process. Very recently, from the comparison of the excess electron migration rate through DNA with the debromination rate of BrU or cleavage rate of T dimer, they suggested that the hopping rate through (A:T)₄ pair is faster than $1.8 \times 10^7 \text{ s}^{-1}$ (T dimer cleavage) and slower than $1.4 \times 10^8 \text{ s}^{-1}$ (BrU debromination).⁸¹

In the series of their study on the excess electron transfer using flavin donor, they have also revealed that the formation of the duplex structure is essential for the excess electron transfer. In addition, the absence of any effect of N₂O gas saturation on the excess electron transfer rate eliminates the possibility of the contribution of the solvated electron, which can be generated by electron ejection from the photoexcited donor to solvent to mediate negative charge to the acceptor, on excess electron transfer.⁸² Thus, the excess electron transfer is mediated by nucleobases in DNA. This is another important information obtained from their studies.

Ito and Rokita have investigated the excess electron transfer using DNA conjugated with *N,N,N',N'*-tetramethyl-1,5-diaminonaphthalene (TMDN) and BrU, as the photosensitizing electron donor and acceptor, respectively (Figure 18).^{83,84} Selective excitation of TMDN causes the excess electron injection to DNA and its reach to BrU to generate radical anion, which results in decomposition of the 5' neighbor by generation of U radical, H abstraction, and hydrolysis, as indicated in Figure 18. The yield of the electron transfer to BrU was evaluated by electrophoresis. In 2003, they found the smaller distance dependence of the yield of reduced BrU, which is in accordance with the results of Carell *et al.*, indicating the excess electron migration by hopping mechanism. Furthermore, in 2004, using the DNA described in Figure 19, they clarified the following points: (i) The excess electron transfer becomes efficient when the donor and acceptor are separated by T rather than C (Figure 19), especially when the distance is the same. The contribution of the C radical anion to the excess charge transfer is limited by the preferential protonation of the C

radical anion. This issue was confirmed by the isotope effect using D₂O solvent, which affects DNA with C but not T. From this, they suggested that the T is a primary carrier of the excess electron. (ii) The interstrand excess electron transfer is slower than intrastrand transfer. The electron transfer from 3' to 5' is faster than that in the reverse direction. This trend is opposite to that for the hole migration in DNA. They pointed out the difference in the MO contributing to each carrier migration, that is, HOMO for the hole migration and lowest unoccupied molecular orbital (LUMO) for the excess electron migration. These findings were not observed by Carell *et al.* as indicated above because the slower splitting rate of the T dimer on reduction acted as the rate-determining step.

As summarized in this section, important information on the excess electron transfer in DNA has been obtained from studies based on biochemical assay. According to these results, DNA, especially T, acts as the major mediator of the excess electron transfer, while C has a minor contribution because of the protonation by G, which forms a pair with C, and surrounding water. The distance dependence of the excess electron transfer yield gives a β value of 0.1–0.3 Å⁻¹, which is in accordance with the multi-step hopping conduction of the excess transfer as in the case of the hopping mechanism of the hole transfer. This was confirmed as the excess electron transfer yield obeys the single-step random walk model, as indicated by Carell *et al.* The absence of any contribution from the hydrated electron to the excess electron transfer is another important information obtained from their research results. The tendencies observed by Ito and Rokita are quite interesting to be clarified by more detailed studies. Compared to the hole transfer, on the other hand, the rate constant of the single excess electron transfer has not been determined. For determination of the rate constant, kinetic information based on the time-resolved study is essential. In the next section, time-resolved spectroscopic studies on the excess electron transfer are summarized.

4.3 Excess Electron Injection to DNA

In 1999, the research groups of Lewis and Wasielewski investigated the electron injection from the photoexcited SD, which was introduced at

Figure 18 DNA conjugated with the TMDN and BrU as the electron donor to DNA and acceptor, respectively. [Reproduced with permission from Ref. 84. © Wiley-VCH Verlag GmbH & Co. KGaA, 2004.]

the loop position of the DNA hairpin, by the femtosecond transient absorption spectroscopy.⁸⁵ They found the formation of the SD radical cation within ~ 0.2 ps, when T is located next to SD, indicating the excess electron injection to T. Using the hairpin DNA with SD at the loop position, they have also investigated the distance dependence of the excess electron injection, in the subsequent study.⁸⁶ In the study, they inserted a noncanonical G : G base pair between SD and A : T pairs (Figure 20), in order to ensure that G acts as a barrier for the excess electron injection process without the contribution of C, which is also a possible candidate for the electron acceptor from the photoexcited SD. Actually, they confirmed that the electron injection to C occurred with a rate constant of $3.3 \times 10^{11} \text{ s}^{-1}$,

which is slower than that for T ($> 2 \times 10^{12} \text{ s}^{-1}$) due to smaller driving force of the excess electron injection. In addition, they evaluated the electron transfer rate from excited SD to I : C pair to be $1.4 \times 10^{12} \text{ s}^{-1}$, which is much faster than that of G : C pair due to the enhancement of the electron accepting ability of C as a result of base pairing. The electron injection rate was decreased to 5.7×10^9 and $4.4 \times 10^8 \text{ s}^{-1}$ when one and two G : G pairs, respectively, were inserted between SD and T. They pointed out that these rates are circa 25 times slower than those of the hole injection from the singlet-excited SA, in spite of similar driving force for the charge separation. They attributed this difference in the charge injection rate to the longer D–A distance or weak D-bridge-A electronic coupling probably due

Figure 19 Strand scission rates of DNA conjugated with TMDN and BrU (Figure 18) after UV irradiation and piperidine treatment. [Reproduced with permission from Ref. 84. © Wiley-VCH Verlag GmbH & Co. KGaA, 2004.]

to G : G base pair as evident from the lower melting temperature of multiple G : G inserted samples.

In 2009, the research groups of Lewis and Fiebig investigated the charge injection process of the DNA with aminopyrene (APy) as an end-capping group.⁸⁷ They found a charge separation time of 0.55 ps from the photoexcited APy to T, while the charge separation time decreased to 0.27 ps when BrU was located as the first or second neighbor of APy. The reduction of BrU was evaluated by HPLC or MALDI-TOF mass spectroscopy. The distance dependence of the yield of the reduced product has been indicated in Figure 21, in which the hole transport yield in SA-An-SD is also plotted. The slope of the plot is almost parallel to each other, supporting the hopping transport of excess electron along the DNA. These results are in accordance with those Carell *et al.* and Ito and Rokita described in the former section.

Wagenknecht and coworkers also investigated the process of injection of excess electron to DNA.⁸⁸ In 2004, they investigated the photoinduced process of pyrene-conjugated U and C (PydU and PydC, Figure 22).^{89,90} In their case, PydC showed weak pH dependence (pH 5 or 11), while the electron transfer in PydU was completely inhibited at higher pH. The observation with PydC can be explained on the basis that the C radical anion is protonated even under basic aqueous condition on a picosecond

Figure 22 PydU and PydC and schematic energy diagram for the charge separation and protonation. [Reproduced with permission from Ref. 88. © Wiley-VCH Verlag GmbH & Co. KGaA, 2003.]

timescale. The difference in the degree of the proton association to C radical anion varies with the charge recombination rate. In the case of PydU, on the other hand, relative high energy of unprotonated U radical cation inhibited the formation of the radical ion pair. They pointed out that the observed pH dependence is also important for the electron transfer in DNA, that is, protonated C radical anion, which should be generated by complement base G or surrounding water, will limit or terminate the electron migration in DNA. Thus, they suggested that C radical anion cannot act as charge carrier.

In a subsequent study in 2005, Wagenknecht and coworkers investigated the excess electron transfer in DNA using PTZ as the electron donor and BrU as the acceptor.⁹¹ The efficiency of the excess electron migration was confirmed by yield of the strand cleavage. In the article, they confirmed that the A : T base pairs transport electron more efficiently than G : C pair owing to proton transfer of C radical anion from the pairing G. This result is consistent with those of Ito and Rokita.

As summarized in the sections on the excess electron transfer in DNA, the electron injection process

has been investigated by both biochemical assay and transient absorption spectroscopy. On the other hand, the migration process in DNA was revealed mainly by biochemical assay. As seen in the investigations of the hole migration process in DNA, the donor–DNA–acceptor system, of which the acceptor radical anion is detectable with transient absorption spectroscopy, should be quite useful for the detailed

analysis of the excess electron transfer processes. From this point, our research group has investigated the excess electron transfer in DNA hairpin conjugated with APy and diphenylacetylene (DPA), as the photosensitizing electron donor and electron acceptor at loop position, since the DPA radical anion is known to show a sharp absorption band around 490 nm (Figure 23).⁹² In order to enhance

Figure 23 DNA hairpin conjugated with APy and DPA as the electron donor and acceptor, respectively. [Reproduced from Ref. 92. © American Chemical Society, 2010.]

the yield of the DPA radical anion as a result of the excess electron migration to DPA, dihydrothymine (^DT), which acts as a barrier for the rapid charge recombination,⁹³ was inserted between APy and T. From the femtosecond transient absorption spectroscopy, it was revealed that the excess electron injection to T was completed within 10 ps even in the presence of ^DT between APy and T. The generated APy radical cation was deactivated by the charge recombination to form ground state APy with a time constant of 51 ps. Thus, a major part of the injected charge recombined with the APy radical cation. The formation of the DPA radical anion was not observed within our time window of the pump-probe apparatus. On the other hand, DPA radical anion was clearly observed immediately after the nanosecond laser excitation (Figure 24a), indicating that the time for the hole migration should be shorter than 10 ns. Thus, the time constant for the excess electron migration cannot be determined from our experiment. On the other hand, absorbance of the generated DPA radical anion should reflect the efficiency of the excess electron migration. In Figure 24b, large ΔA of hairpin **8** indicates successful retardation of the charge recombination in ^DT -inserted DNA hairpin. From a comparison of **8**, **11**, **12**, and **13**, it was revealed that the mismatch sequence decreased the yield of the DPA radical anion, as in the case of the hole migration (Figure 24c). Furthermore, insertion of C also decreased the yield as seen by the comparison of **14**–**18**. These findings indicated that the discussion based on the biochemical assay can also be discussed on the basis of the yield of DPA radical anion. Furthermore, it was revealed that the electron can migrate even when the APy and DPA were separated by 10 base pairs, that is, 34 Å.

In this section, investigations on the electron injection process by time-resolved spectroscopic method were summarized. Compared to hole injection process, our understanding of the electron injection process is fragmented. In each case, the rate constant for the charge injection process is clarified. But detailed insights into excess electron injection, such as driving force dependence, reorganization energy, electronic coupling, distance dependence, structural fluctuation effect, and so on, have not been obtained. For these issues, further investigations using donor–DNA–acceptor systems have to be carried out. On the other hand, protonation

effect on the excess charge transfer is an interesting phenomenon because DNA always forms its structure via hydrogen bonding and is always surrounded by water. The crucial role perhaps will be included.

4.4 Summary for Excess Electron Transfer in DNA

As summarized in this article, several information on the excess electron transfer have been obtained from the investigation of several researchers. For an electron injection process, excess electron transfer proceeds on the timescale of the picoseconds when the driving force of the charge separation is enough exothermic. The nucleobases that accept electron from the donor are the pyrimidine bases, while C radical anion is easily protonated because of G, which forms a pair with C, or surrounding water, to diminish its role as a charge carrier. Once the electron is injected into the DNA, it can migrate in DNA by a hopping mechanism as evidenced by the random walk model. Except for the protonation process, the electron injection and migration processes have similarity to those of the hole migration. On the other hand, as revealed by Ito and Rokita, preference direction of the excess electron migration was different from that of the hole transfer. Furthermore, as pointed out at the end of the former section, details of the mechanism are not cleared in the case of the excess electron transfer. For the systematic understanding of the excess electron transfer, sequence dependent electron transfer rates have to be determined. These issues will be realized in near future.

5 SUMMARY

In this article, we have summarized charge transfer in DNA. Owing to the efforts of the scientists in the past two decades, detailed mechanisms for the charge transfer, especially the hole transfer, became clearer. It was revealed that the basic mechanisms for the charge injection and single-step charge transfer can be described by the Marcus theory, indicating that the interaction between the donor and acceptor for the charge transfer is not very strong. By one-dimensional random walk mechanism, hole and excess electron can migrate rather longer distance such as hundreds of angstroms. These points seem to be widely accepted, although the information on the excess electron transfer is not sufficient at the present stage. But these information on the excess electron transfer as well as the properties specific to excess electron transfer, such

as protonation effect in the electron transfer rate, will be cleared in future.

In addition to these information on the charge transfer in DNA duplex, charge transfer in other higher order structure is another interesting subject, because such study will enlarge the possibility of application of DNA to the nano-constructed materials and biomedical purpose. In spite of some reported studies, clarification of the charge transport in them is still not satisfactory. In addition, relation with proteins is another interesting point when the importance of the charge conduction in the biomedical sense is considered. These studies will give important information in both biochemistry and nanotechnology in future.

ACKNOWLEDGMENTS

We are grateful to a number of collaborators, especially Professor Kiyohiko Kawai and Professor Takashi Tachikawa, SANKEN, Osaka University. We thank the members of the Radiation Laboratory, SANKEN, Osaka University, for running the linear accelerator. This work has been partly supported by a Grant-in-Aid for Scientific Research (Project 21350075, 22245022, Priority Area (477), and others) from the Ministry of Education, Culture, Sports, Science and Technology (MEXT) of Japanese Government. T. M. thanks WCU (World Class University) program through the National Research Foundation of Korea funded by the Ministry of Education, Science and Technology (R31-10035) for the support.

Understanding DNA Radicals Employing Theory and Electron Spin Resonance Spectroscopy

Amitava Adhikary, Anil Kumar, David Becker and Michael D. Sevilla

Department of Chemistry, Oakland University, Rochester, MI, USA

1 INTRODUCTION

Genetic information in living systems is stored in DNA molecules in a four letter code of DNA bases, A, T, G, and C, with specific pairing of DNA bases—A with T and G with C. Perturbations of the DNA structure can profoundly affect the performance and survival of organisms. Experimental evidence indicates that damage to DNA is a cause of cell death, mutation, and neoplastic transformation.^{1–3} Among the various types of DNA damage, strand breaks are known to be among the most biologically significant lesions as they disrupt the structural continuity and integrity of the double helix, with the double-strand break a potentially lethal lesion.^{4–6} It has been well established that free radicals on the deoxyribose moiety of DNA are immediate precursors to DNA strand breaks.^{4,7–9} Damage to the DNA bases is usually repairable but can lead to point mutations and subsequent dysfunction. Both sugar and base damage in DNA are chiefly caused by free radical processes. It has been well established that various types of free radicals on DNA (DNA radicals, see Section 1.1)—cation, anion, and neutral—can be stabilized at low temperature and, hence, be studied by employing electron spin resonance (ESR) spectroscopy.^{10–16} Moreover, owing to the tremendous technological development

in computational chemistry in both computer hardware and software,¹⁷ theoretical molecular orbital (MO) calculations have provided substantial aid in the understanding of the mechanisms of formation of radiation-induced DNA radicals and their subsequent reactions to strand breaks.^{18–20} The focus of this article is to illustrate how ESR, along with theoretical *ab initio* MO studies have contributed to an understanding of the properties of various DNA radicals and to elucidate the mechanisms of formation of DNA damage products via these DNA radicals.

1.1 Radicals Formed in DNA (DNA Radicals)

1.1.1 Pathways of Formation

DNA radicals are produced via various pathways, viz.,

- (i) *Ionizing radiation*: Radiation damage to DNA occurs via two principal processes: the direct and the indirect effects.⁷ The direct effect corresponds to the direct deposition of energy in the DNA molecule itself resulting in the formation of cation ($\text{DNA}^{+\bullet}$) and anion radicals ($\text{DNA}^{\bullet-}$). A consideration of the interface between DNA and its surroundings led

Scheme 1 Formation of DNA cation and anion radical via direct-type effects. ht, hole transfer; et, electron transfer.

to the recognition of the quasi-direct effect in which ionization in the first solvation shell of water leads to transfer of holes and electrons to nearby DNA leading to additional DNA cation and anion radical production.^{10–16} Several experiments have shown that DNA's first 8–10 waters of hydration act in this manner.^{10,12–14} The direct and quasi-direct effects are collectively known as *direct-type effects* as shown in Scheme 1.

For the indirect effect, the energy is deposited into the surroundings, for example, bulk water, proteins thereby producing the radicals (e.g., HO•, e[−], and H• for water)

Scheme 2 Formation of DNA radical via indirect effect by HO• mostly (circa 80%) at the DNA bases. H-atom abstraction by HO• from the deoxyribose sugar moiety (circa 20%) leads to the formation of neutral sugar radicals.

(see **Radiation-Induced Radical Reactions**). The most damaging radical is HO• which diffuses to and reacts with DNA to produce DNA radicals with almost diffusion-controlled rates (Scheme 2). The HO• reacts by addition to the base moiety or by abstraction of an H-atom from the deoxyribose sugar moiety in DNA leading to the formation of neutral sugar radicals^{7,21–23} (see also **Oxidatively Generated Nucleobase Modifications in Isolated and Cellular DNA** and **Oxidatively Formed Sugar Radicals in Nucleic Acids**).

Scheme 3 Structures of DNA radicals discussed in this article.

Scheme 4 DNA radicals formed via oxidative (i.e., electron loss) pathway. Via hole transfer processes, the hole is localized on the guanine base. The sugar radicals, especially $C3''\cdot$ and $C5''\cdot$, which are known as *strand break precursor radicals*, are produced either via direct ionization of the sugar–phosphate backbone or via excitation of $G^{\bullet+}$. Here, “ht” denotes hole transfer and “ssb” means single strand break.

Scheme 5 DNA radicals formed via the reductive (i.e., electron gain) pathway. Via electron transfer, the electrons are localized on cytosine and thymine bases, where subsequent reversible ($C(N3H)\cdot$) and irreversible ($TH\cdot$) protonation reactions occur. The sugar radicals, especially $C3''_{\text{dephos}}\cdot$ and $C5''_{\text{dephos}}\cdot$, which are immediate strand break radicals, are produced via dissociative electron attachment of the low-energy electrons (≤ 20 eV) at the sugar–phosphate backbone. Here, “et” denotes electron transfer and “ssb” means single strand break.

For the structural formulae of sugar radicals see Scheme 3.

- (ii) *DNA radical formation by metal-mediated formation of oxyl radicals*: DNA radicals are produced via attack of oxyl radicals formed by complexed metals (e.g., Fe^{2+} and Cu^{2+}) with endogenous hydroperoxides.^{7,23,24}
- (iii) *Other methods*: DNA radicals are also produced via other exogenous methods, for example, UV photolysis (e.g., via Norrish type I and II reactions), and also endogenously via attack of reactive oxygen and reactive nitrogen species.^{7–9}

It has already been mentioned in Section 1 that the thrust of this article is to review radical formation

and trapping in low temperature irradiated DNA, and, to describe the radical processes that likely lead to strand breaks. Ionizing radiation, such as γ -radiation, X-rays, or ion beams initially results in formation of cation radicals, anion radicals, and excited states (Schemes 1, 4, and 5) in the medium being irradiated. Secondary radicals (see Schemes 3–5 and also Section 3) result from the chemical reactions of these primary radicals.

At 77 K in DNA, these radicals can be trapped and observed using ESR spectroscopy. In Figure 1, the ESR spectrum, at 77 K, of DNA, hydrated to $\Gamma = 12$ D_2O /nucleotide, and γ -irradiated to 8.8 kGy is shown.^{10–12} Computer analysis of the spectrum using a least squares method and the benchmark spectra shown in Figure 1 indicates that

Figure 1 (a) ESR spectrum of hydrated ($\Gamma = 12$ D₂O/nucleotide) DNA, γ -irradiated to 8.8 kGy; the DNA was irradiated and the spectrum recorded at 77 K. This spectrum is a composite, arising from at least seven trapped radicals. (b)–(e) Benchmark spectra used to computer analyze the DNA spectrum. See narrative for description of each species. The three reference markers in this figure and in other figures show the position of the Fremy's salt resonances with the central marker at $g = 2.0056$. Each of these markers is separated from each other by 13.09 G.

the spectrum is actually a composite that results from the presence of at least seven radicals. Three of these are the base radicals: G(–H) $\cdot$, C(N3)H $\cdot$, and T $\cdot^-$ (Scheme 3). Individual benchmark ESR spectra (Figure 1) for each of these have been developed. The other four radicals are the sugar radicals: C1' $\cdot$, C3' $\cdot$, C5' $\cdot$, and C3' $\cdot_{\text{dephos}}$ (Scheme 3). These are radicals in which the unpaired electron resides on the deoxyribose sugar ring. Invariant individual benchmark spectra cannot be successfully developed for each these radicals as they change couplings with conformation, but a composite spectrum from them, labeled $\Sigma\text{dR}\cdot$, can be successfully used as a single benchmark for analysis of the overall DNA spectrum. Spectral components from C1' $\cdot$, C3' $\cdot$,

C5' $\cdot$, and C3' $\cdot_{\text{dephos}}$ are present in $\Sigma\text{dR}\cdot$, indicating that these radicals are present in the DNA radical composite spectrum. However, analysis of $\Sigma\text{dR}\cdot$ has been able to account for only circa 85% of the spectral intensity present; hence, there may be other, as yet unidentified, radicals present. Theoretical calculations have been critical in determining the nature and origin of all seven of the known radicals in γ -irradiated hydrated DNA (*vide infra*).

A large number of the initial DNA radicals, including those shown above, result from the DNA cation and anion radicals originating with ionizations via direct-type effects (Scheme 1). The two principal ionization pathways for DNA radical formation are the electron loss (or oxidative path, Scheme 4) and the electron gain (or reductive path, Scheme 5).^{7,10–16,20} In Schemes 4 and 5, those radicals that contribute to the ESR spectrum shown in Figure 1 are shown with boxes around them.

1.1.2 DNA Radicals and the Oxidative (Electron-Loss) Pathway

For the oxidation pathway (Scheme 4), the ionization of DNA occurs at both the bases and the sugar group. Ionization through the Compton effect is roughly proportional to the number of valence electrons; thus, about half the ionization occurs at the DNA bases and half at the sugars as indicated in the scheme.¹⁰ Of the four possible oxidized bases, only G(–H) $\cdot$ is trapped and observed at 77 K in double stranded (ds) hydrated DNA.^{25–27} This is quite reasonable since guanine has the lowest ionization energy of the four bases.^{28–30} To explain this observation, hole transfer (ht) must occur as indicated to localize the hole on guanine to first give C : G $^{+\cdot}$, which then undergoes intra-base pair proton transfer from the N1 of guanine to the N3 on cytosine to give C(+H $^{+\cdot}$) : G(N1–H) $\cdot$, the radical that is trapped and observed at 77 K (Section 3.1.4).^{25–27,31} Owing to the nucleophilic addition of water at the C-8 atom in the guanine moiety of C : G $^{+\cdot}$, and via subsequent deprotonation, a guanine OH-adduct radical (GOH $\cdot$) is formed.^{32,33} The diamagnetic compounds 8-*oxo*-G and FapyG are formed via one-electron oxidation and one-electron reduction of GOH $\cdot$, respectively.^{7,34}

Electron loss at the deoxyribose sugar results in a hole on the sugar (dRib $^{+\cdot}$) (Scheme 4). Sugar cationic radicals have not been observed

in polymeric DNA at 77 K. It is assumed that rapid deprotonation from C1', C3', or C5' sites in dRib⁺ leads to formation of C1'', C3'', and C5'', respectively.^{7,12} These radicals contribute to the Σ dR⁺ benchmark spectrum shown in Figure 1. On warming, they cause base release and/or a single strand break.^{7–9}

One remaining pathway in the electron loss regime involves proton-coupled hole transfer (PCHT) from an excited base cation radical to the deoxyribose sugar. As shown in the scheme, the deoxyribose sugar cation radical thus formed rapidly deprotonates, resulting in a neutral sugar radical such as C1'', C3'', or C5'' (see also Section 3). Deprotonation is expected to occur within the lifetime of the excited state (circa 10^{-12} s (Section 3.2.1)); hence, formation of a neutral sugar radical contributing to product formation should be very rapid.^{10–12,16,18,19,35,36}

1.1.3 DNA Radicals and the Reductive (Electron-Gain) Pathway

The electron gain path results from the localization of ionization produced electrons principally on DNA bases after electron thermalization. The actual DNA base locations of initial electron trapping are likely to be random on all four bases. However, the trapped radicals observed are from electron addition to C and T bases^{7,10–16,20}; thus, only T^{•−} and C(N3)H^{•−} are trapped and observed at 77 K.^{10–16,20} This is plausible because the pyrimidine bases have greater electron affinities than the purines.^{18–20} It is reasonable to postulate that electron transfer (et) must occur in order to explain the trapping of only the pyrimidine base anionic radicals and not any purine base anionic radicals in the electron gain path.^{10–16,20} Reversible proton transfer from N1 on guanine to N3 on the anionic cytosine radical (C^{•−}) results in ultimate formation and trapping of C(N3)H^{•−} at 77 K.^{7,10–16,20}

Nonthermal electrons, that is, low-energy electrons (LEEs), have been shown to induce reactions at the sugar phosphate backbone. This provides a second pathway for the electron gain product formation (Section 3, Scheme 10).³⁷ LEEs are electrons that have energies of near 0 to circa 20 eV and which have not been solvated.^{10–16,18–20,37} They can add to the DNA and cause an immediate strand break

through a dissociative electron attachment (DEA) process (see Section 3.2.2 for a comprehensive discussion).

1.2 Identification of DNA Radical Hyperfine Interaction: Theory and Experiment

The identification of DNA radicals using ESR spectroscopy in conjunction with theory is briefly outlined below. Those further interested should also consult article **Analysis of Radicals by EPR**.

From Section 1.1, it is evident that in the absence of molecular oxygen, two main types of DNA radicals are produced via ionization processes, purine and pyrimidine radicals, and carbon-centered sugar radicals.⁷ In these DNA radicals, the unpaired spin on the radical site interacts with nuclei that have magnetic moment, such as, ¹H, ²H, and ¹⁴N. This electron spin–nuclear spin interaction gives rise to hyperfine coupling, which is characterized by the hyperfine coupling constant (HFCC) values. The HFCC values along with the *g*-value affect the ESR spectra of these radicals.^{38–43} The HFCCs, represented by a tensor (see Section 2 for details), consists of (i) an isotropic (Fermi contact term) and (ii) anisotropic (dipolar) terms.^{38–43} The isotropic part depends on the interaction of the unpaired electron at a magnetic nucleus and is known as the *Fermi contact interaction*. Its measurement is directly proportional to the electron spin density at the nucleus. On the other hand, the anisotropic coupling is obtained from the classical expression of two interacting magnetic dipoles and its value depends on the overall distribution of spin in the molecule away from the nucleus.^{38–43} The anisotropic hyperfine couplings average to zero for rapidly tumbling radicals in nonviscous solutions at room temperature. Thus, in solutions, only the isotropic interactions are observed by EPR. The isotropic hyperfine coupling is dealt with in detail in article **Analysis of Radicals by EPR**. Owing to the nature of systems involving biomolecules at low temperatures (e.g., hydrated biomolecules, biomolecules in frozen aqueous solutions at low temperatures, or irradiated single crystals of model compounds), both the isotropic and anisotropic hyperfine couplings are observed in these systems.^{10–16,20} Hence, in

Section 2, the theoretical background of the hyperfine interaction with special emphasis on anisotropic hyperfine couplings is presented.

The anisotropic portion of the HFCC is more easily calculated by theory than the contact term. Theoretical calculation of accurate isotropic HFCCs (contact term) is a complex task because the spin density at the nucleus depends on the radical structure and conformation, electron correlation effects, and a number of mechanisms of spin delocalization, such as, spin polarization for an α -proton coupling and direct hyperconjugation for a β -proton coupling.^{44–49} Computation of HFCCs by quantum chemical methods have employed all levels of theory including Hartree–Fock (HF), Møller–Plesset perturbation theory (MP2), coupled cluster (CC), multiconfiguration self-consistent field (MCSCF), multireference configuration interaction (MRCI), and density functional theory (DFT). From a number of studies, it was found that the HF method is not adequate to compute the isotropic HFCCs; the post-HF electron correlated methods (MP2, CC, MCSCF, and MRCI) are very computationally expensive and feasible for small molecules only.^{50–53}

DFT using the B3LYP functional is found to predict isotropic HFCCs with good accuracy.^{51,54–64} The use of DFT has several advantages such as (i) reduced computational cost comparable to HF methods. (ii) It can be applied to large molecules of up to approximately 1000 atoms. (iii) It takes into account electron correlation through the exchange–correlation function. Finally, (iv) it provides reasonably accurate molecular geometries.⁵³ In this context, we mention recent reports by Hermosilla *et al.*,^{65–67} in which, these authors extensively considered a large number of radicals, anionic, cationic, and neutral, containing ¹H, ⁹Be, ¹¹B, ¹³C, ¹⁴N, ¹⁷O, ¹⁹F, ²³Na, ²⁵Mg, ²⁷Al, ²⁹Si, ³¹P, ³³S, and ³⁵Cl nuclei and calculated the isotropic HFCCs using B3LYP, B3P86, and B3PW91 density functionals and 6-31G*, TZVP, EPR-III, and cc-PVQZ basis sets. The calculated 274 HFCC values were compared with the available 174 experimental HFCC values.⁶⁵ They also calculated the ¹⁴N isotropic HFCCs of 109 radicals containing a nitrogen atom. From a regression analysis,^{65,66} they find the B3LYP method to be reliable in predicting the isotropic HFCCs of these radicals. Furthermore, the B3LYP method has showed its applicability in predicting a variety of the properties

of DNA ion radicals, for example, conformation, spin density distribution, energies for hole and anion formation, acid/base properties of DNA base radicals, potential energy surfaces for proton transfer between one-electron oxidized Watson–Crick DNA base pairs, and sugar radical formation from excited one-electron oxidized nucleosides, nucleotides, and oligomers. These will be elaborated, along with experimental ESR findings in subsequent sections. In addition to HFCC computation, B3LYP and PBE0 density functionals with the N07D basis set by Barone and Cimino⁶⁸ were found to predict “remarkably accurate” electronic *g*-tensor values for a number of free radicals of second row elements.

2 ANISOTROPIC HYPERFINE INTERACTION AND COUPLING

2.1 The Complete Spin Hamiltonian

Usually DNA radicals (see Section 1.1) have the unpaired electron located in a p-orbital or a delocalized π -MO.³⁹ The electron in a p-orbital is distributed away from nucleus in space; so, the interaction between the electron spin and nuclear spin produces a magnetic dipole–dipole interaction that is called the *dipolar hyperfine interaction*. This type of interaction is anisotropic in nature, that is, the magnitude of this interaction as well as its sign depends on the orientation of the radical to the external magnetic field. The hyperfine splitting resulting from this type of interaction is called *anisotropic hyperfine splitting*.

The Hamiltonian for the electron–nuclear magnetic dipole–dipole interaction is given by (1)^{38–43}:

$$\hat{H}_{\text{dipolar}} = \frac{\vec{\mu}_e \cdot \vec{\mu}_N}{r^3} - \frac{3(\vec{\mu}_e \cdot \vec{r})(\vec{\mu}_N \cdot \vec{r})}{r^5} \quad (1)$$

where $\vec{\mu}_e$ is the magnetic moment of the electron, which is equal to $-g_e\beta_e S$, $\vec{\mu}_N = g_N\beta_N I$ is the magnetic moment of the nucleus, and $\vec{r}$ is the vector joining the unpaired electron and the nucleus. Here, g_N is the nuclear *g*-value, g_e is the *g*-value of the free electron, β_N is the nuclear magneton, and β_e is the Bohr magneton. Equation (1) expresses the classical dipole–dipole interaction between two magnetic moments.^{38–43}

The magnetic moments can be replaced by their corresponding operators in a quantum mechanical

system. Therefore, the anisotropic interaction in (2) can be modified as^{38–43}

$$\hat{H}_{\text{dipolar}}(r) = -\frac{\mu_0}{4\pi}(\mathbf{g}_e\beta_e\mathbf{g}_N\beta_N) \times \left[\frac{\hat{\mathbf{S}} \cdot \hat{\mathbf{I}}}{r^3} - \frac{3(\hat{\mathbf{S}} \cdot \vec{r})(\hat{\mathbf{I}} \cdot \vec{r})}{r^5} \right] \quad (2)$$

Here, $\hat{\mathbf{S}}$ is the electron spin operator and $\hat{\mathbf{I}}$ is the nuclear spin operator. Here, $\hat{\mathbf{S}} = \hat{S}_x\hat{\mathbf{i}} + \hat{S}_y\hat{\mathbf{j}} + \hat{S}_z\hat{\mathbf{k}}$, $\hat{\mathbf{I}} = \hat{I}_x\hat{\mathbf{i}} + \hat{I}_y\hat{\mathbf{j}} + \hat{I}_z\hat{\mathbf{k}}$, and $\vec{r} = x\hat{\mathbf{i}} + y\hat{\mathbf{j}} + z\hat{\mathbf{k}}$.

Application of this Hamiltonian in (2) to an electron in an orbital leads to its average over the entire electron spatial distribution and that is abbreviated as follows^{40–43}:

$$\hat{H}_{\text{dipolar}}(r) = \hat{\mathbf{S}} \cdot \mathbf{T} \cdot \hat{\mathbf{I}} \quad (3)$$

Here, $\mathbf{T}$ is the dipolar interaction tensor (in units of MHz or Gauss), which expresses the anisotropic nuclear hyperfine interaction. Hence, the complete static Hamiltonian operator is^{40–43}

$$\hat{H} = \beta_e\hat{\mathbf{S}} \cdot \mathbf{g} \cdot \vec{H} + \hat{\mathbf{S}} \cdot \mathbf{A} \cdot \hat{\mathbf{I}} - g_N\beta_N\vec{H} \cdot \hat{\mathbf{I}} \quad (4)$$

where $\beta_e\hat{\mathbf{S}} \cdot \mathbf{g} \cdot \vec{H}$ represents the electron Zeeman term, $\hat{\mathbf{S}} \cdot \mathbf{A} \cdot \hat{\mathbf{I}}$ is the hyperfine interaction term, and $g_N\beta_N\vec{H} \cdot \hat{\mathbf{I}}$ is the nuclear Zeeman term. H is the external magnetic field. Note that the contribution from the nuclear Zeeman term is generally neglected in the interpretation of ESR spectra as it does not affect the EPR spectrum. Thus, (4) becomes^{40–43}

$$\hat{H} = \beta_e\hat{\mathbf{S}} \cdot \mathbf{g} \cdot \vec{H} + \hat{\mathbf{S}} \cdot \mathbf{A} \cdot \hat{\mathbf{I}} \quad (5)$$

In (4) or (5), $\mathbf{g}$ and $\mathbf{A}$ are tensors and are 3×3 matrices representing the anisotropic electron Zeeman and nuclear hyperfine interactions. In general, a coordinate system can be found (the principal axes) in which $\mathbf{g}$ and $\mathbf{A}$ are diagonal. If $\mathbf{g}$ and $\mathbf{A}$ are diagonal in the same coordinate system, their principal axes are said to be coincident. $\mathbf{A}$ is the sum of the scalar term a , which is the isotropic component (Fermi contact term), and $\mathbf{T}$, which is the anisotropic component (the dipole–dipole interaction term), that is,^{40–43}

$$\mathbf{A} = \mathbf{T} + a \cdot \mathbf{1} \quad (\mathbf{1} = \text{unit matrix}) \quad (6)$$

These expressions are valid for any orientation of the radical with respect to the applied field. For

a spherical electron cloud or for radicals which are rapidly tumbling in solution, $\hat{H}_{\text{dipolar}} = 0$, and both $\mathbf{g}$ and $\mathbf{A}$ become scalar quantities. For those cases, the hyperfine coupling becomes isotropic and is equal to one third of the trace of the anisotropic $\mathbf{A}$ diagonalized tensor. In solid samples such as single crystals or aqueous glasses, where $\hat{H}_{\text{dipolar}}$ is not equal to 0, for interpretation of the ESR spectrum of a radical, the evaluation of the full anisotropic $\mathbf{g}$ (the $\mathbf{g}$ -tensor) and of the full anisotropic $\mathbf{A}$ (the $\mathbf{A}$ -tensor) in (5) are necessary.

2.1.1 The $\mathbf{g}$ -Tensor

The anisotropic $\mathbf{g}$ -tensor can be represented by the following 3×3 matrix (Scheme 6)^{40–43}:

On diagonalization of the $\mathbf{g}$ -tensor, three principal values, g_{xx} , g_{yy} , and g_{zz} , are found whose principal eigenvectors correspond to directions in the molecular framework (g_{zz} , e.g., is usually coincident with the z -axis of the p_z orbital in a π -electron-type radical). For a particular radical, the deviation of the radical $\mathbf{g}$ -value from the $\mathbf{g}$ -value of the free electron ($g_e = 2.0023$) arises from the coupling of spin and orbital angular momenta ($\lambda L \cdot S$), λ is the spin-orbit coupling constant. This effect is increased with atoms of higher atomic number (Z), which have greater tendency to couple spin and orbital angular momenta than do lighter atoms. Thus, N, O, S, and Cl atoms show a progressive increase in deviation from g_e with increasing atomic number (Z). As a rule of thumb, the greater the spin on the heteroatom in the radical, the greater is the deviation from g_e .

For most DNA radicals (see Section 1.1), the $\mathbf{g}$ -values found (2.002–2.006) are close to the free spin value ($g_e = 2.0023$).^{10–16,20,39} For these radicals, only small differences in the three principal $\mathbf{g}$ -values are experimentally detected. Often

$$\begin{bmatrix} g_{xx} & g_{xy} & g_{xz} \\ g_{yx} & g_{yy} & g_{yz} \\ g_{zx} & g_{zy} & g_{zz} \end{bmatrix} \xrightarrow{\text{Diagonalization}} \begin{bmatrix} g_{xx} & 0 & 0 \\ 0 & g_{yy} & 0 \\ 0 & 0 & g_{zz} \end{bmatrix}$$

Scheme 6 Schematic representation of the $\mathbf{g}$ -tensor. Here, x , y , and z -axes are arbitrary axes, which can be the crystal axes in a single crystal. The diagonalized tensor gives the principal axes that correspond to directions in the molecular framework.

the large linewidths in solids, especially for carbon-centered sugar radicals with β -proton couplings only, the small g -value differences cannot be discerned and only one g -value (g -apparent, g_{app}), at the center of the experimentally recorded ESR spectrum is assigned. We note here that the heteroatom (mostly, nitrogen)-centered DNA base radicals have near axial symmetry for both g and hyperfine (A) tensors and hence can be approximated by two g -values, $g_{\parallel}$ and $g_{\perp}$; since g_{xx} is close to g_{yy} , they are both designated as $g_{\perp}$.³⁹ $g_{\parallel}$ is oriented along the direction of the axis of symmetry for the radical p_z orbital and $g_{\perp}$ in the plane of the radical.³⁹

2.1.2 The A-Tensor

Equation (6) shows the nuclear hyperfine interaction term with A diagonalized.

The Fermi contact term (a) in (6) depends on the amount of unpaired electron spin density at the nucleus. Only s-orbitals have spin density at the nucleus and thus only unpaired spin in an s-orbital gives rise to a Fermi contact interaction. The magnitude of this isotropic hyperfine coupling can be used to compute the fraction of s character in the radical if the coupling for unit spin in the s-orbital is known.

The most frequently encountered interacting nucleus is ^1H , which has a nuclear spin $I = 1/2$, and thereby splits the singlet due to an electron into a doublet. In the solid state, two types of proton (^1H) hyperfine interactions exist, viz., isotropic and anisotropic. It is frequently found that the unpaired electron is localized in a single p-orbital on an essentially sp^2 hybridized carbon atom and this circumstance will be used to illustrate the nature of the anisotropic versus isotropic hyperfine interactions. In this discussion, we will also distinguish between an α -proton, which is the one bonded to the carbon atom on which the unpaired electron resides, and which exhibits considerable anisotropy in its hyperfine coupling, and a β -proton, which is a proton bonded to an adjacent carbon, and for which the hyperfine coupling is almost entirely isotropic.

In case of DNA radicals, different types of isotropic hyperfine couplings can be generalized³⁹:

- (i) For π -type radicals in a C–H fragment, this interaction is mediated via spin polarization

Figure 2 Schematic representation of isotropic α -hyperfine interaction via spin polarization. The arrows for the hydrogen and bond must be the same size as they are restricted by the Pauli principle.

(Figure 2), that is, the electrons in the C–H σ -bond are polarized by the unpaired spin and generate a small unpaired spin on the H-atom that is opposite to the unpaired spin density in the carbon p_z orbital (as shown in Figure 2). This is an example of α -proton isotropic hyperfine coupling as the H-atom is directly bonded to the C-atom having the radical site. This induces a small *negative* spin density (circa 4.5%) in the H 1s orbital for a full spin in the p_z on the C-atom. Since the hydrogen atom (for unit spin in 1s orbital) has a HFCC of 506 G, the 4.5% spin gives rise to a -23 G isotropic coupling, which is easily observed experimentally.

- (ii) When the proton is β to the radical site (β -proton) (Figure 3a), its isotropic hyperfine coupling is directly related to the π -spin density (ρ^π) and the dihedral angle (θ) between the C–H bond and z -axis of the carbon p_z orbital at the radical center (Figure 3b) and is given by the following equation:

$$a = B_0\rho^\pi + B_2\rho^\pi\cos^2\theta \quad (7)$$

The value B_2 is near 50 G for typical neutral radicals, for cation radicals, it can be as large as 90 G and for anion radicals as small as 25 G. B_0 is small (0–5 G) and is often neglected. As a result, for a neutral radical, the β -proton isotropic hyperfine coupling for unit spin, ρ^π ranges from near 0 ($\theta = 90^\circ$) to 50 G ($\theta = 0^\circ$) (Figure 3b).

For the anisotropic components (T_{xx} , T_{yy} , and T_{zz}) of the α -coupling in the π -type radicals in a C–H fragment (Figure 2), the three eigenvectors defining the principal axis system are shown in Figure 4. The hyperfine coupling values shown are

Figure 3 (a) The $\text{R-CH}_2\text{-C}^*$ fragment with its p_z -orbital at the radical center. (b) The same radical viewed along the C–C bond axis from the right. The angle θ is the dihedral angle between the C–H bond and the z -axis of the p_z -orbital. The β -proton hyperfine splitting varies with θ .

Figure 4 The figure shows the anisotropic (T_{ii}) and total hyperfine couplings ($A_{ii} = a_{\text{iso}} + T_{ii}$) along the three principal axes in a π -type radical C–H fragment. The external magnetic field, H_0 , when applied along each axis results in the different values of the anisotropic HFCC (T_{ii}).

typical for an α -proton. The observed coupling in the figure for each magnetic field orientation is also calculated using a typical isotropic coupling for an α -proton, circa -20 G . Of course, the actual measured couplings depend on the details of the chemical structure and electronic structure of the radical being investigated. In amorphous solids, all random orientations of the radical relative to the magnetic field (whose direction is fixed) are present, and the observed spectrum is a sum of the individual spectra from each orientation.

A simulated ESR spectrum for a radical with couplings of -10 , -30 , and -20 G , in the x , y , and z directions, as shown in the Figure 4, is shown

in Figure 5a. The spectrum shows the presence of the anisotropic features. In a nonviscous media, in which a radical can tumble rapidly relative to the molecular correlation timescale for the ESR experiment,^{39–43} the anisotropic hyperfine couplings average to zero and only the -20 G isotropic component of the hyperfine coupling is observed resulting in a 20 G doublet (Figure 5b).

For *nitrogen* atoms in DNA base radicals, the unpaired spin is usually localized in the p_z -orbital system, and experimentally, a dipolar hyperfine coupling is observed. The principal values of the anisotropic tensor (T_{xx} , T_{yy} , and T_{zz}) are $(-B, -B, \text{ and } 2B)$. With the applied magnetic field aligned

Figure 5 Simulated ESR spectra for (a) a radical with α -proton couplings of -10 , -30 , and -20 G, in the x , y , and z directions, g (2.0032, 2.0049, 2.0020); for (b), the same radical shown in (a), as it would appear if rapidly tumbling with an α -proton isotropic coupling of -20 G, $g = 2.0034$. These spectra were simulated using 3 G linewidth and a Lorentzian/Gaussian lineshape = 1. The simulated spectra in this figure and in other figures shown in this article were obtained using WIN-EPR and SIMFONIA (Bruker) program.

with the p_z -orbital axis, the magnitude of the anisotropic portion of the coupling is maximum ($2B$). When the external field is perpendicular to the p_z -orbital, the coupling is smaller and reversed in sign ($-B$). Addition of the anisotropic and isotropic terms (a) provides two A -values shown in (8):

$$A_{||} = A_{zz} = (a + 2B), A_{\perp} = A_{xx} = A_{yy} = (a - B) \quad (8)$$

From these values, the sp hybrid character of the radical site can be calculated from the following relationships:

$$\begin{aligned} \%s \text{ character} &= (a/a^\circ) \times 100, \\ \%p \text{ character} &= (B/B^\circ) \times 100 \end{aligned} \quad (9)$$

Here, a° and B° are the isotropic and anisotropic hyperfine couplings calculated for unit populations in pure s - or pure p -orbitals, respectively.

In the past several years, a number of review articles have been published, which have summarized numerous evidences of employing ESR to the identification of DNA radicals.^{7–16,20}

2.1.3 Theoretical Prediction of Radical Properties

ESR provides important information, for example, g -values and HFCCs that can be employed to identify free radicals species. The HFCCs provide the most important information as to the number and kind of magnetic nuclei and their degree of interaction with the unpaired electron in the radical. The HFCCs as well as the molecular geometry of a radical can also be calculated using theory which can confirm radical assignments or prove them poor choices. In recent years, DFT employing the B3LYP functional has been found to be very successful in characterizing DNA radicals.^{69–76} In addition to reliable HFCCs, it provides accurate optimized radical geometries and the relative stabilities of different conformations, vibrational frequencies, and the location of the unpaired electron in the radical. The latter is visualized by plots of spin density distributions as well as plots of the single occupied MO (SOMO). As we have mentioned in Section 1.2, the calculation of an accurate isotropic (Fermi contact term) is difficult for any theoretical method because it is a purely local property and it is very sensitive to the net spin density residing at the nucleus. The isotropic HFCC ($a_{\text{iso}}(n)$) for a nucleus n is directly proportional to the net spin density at the nucleus and is given by^{44,45,58,77}

$$a_{\text{iso}}(n) = \frac{4\pi}{3} g_e g_N \beta_e \beta_N \langle S_z \rangle^{-1} \rho(n) \quad (10)$$

$$\rho(n) = \sum_{\mu\nu} \rho_{\mu\nu}^{\alpha\beta} \langle \phi_\mu | \delta(r_N) | \phi_\nu \rangle \quad (11)$$

In 10, g_e and g_N are electron and nuclear g -factor; β_e and β_N are electron and nuclear Bohr magneton; S_z is the value of the spin quantum number (1/2 for a single unpaired electron) and $\rho(n)$ is the Fermi contact integral for the nucleus. In (11), $\rho_{\mu\nu}^{\alpha\beta}$ is the value of the one electron spin density matrix; ϕ_μ and ϕ_ν are the atomic orbitals and $\delta(r_N)$ is Dirac delta operator.

Generally, all the commonly used quantum chemical methods, for example, HF, B3LYP, MP2, and CCSD, can calculate HFCCs, but the accuracy of the calculated HFCCs is very method dependent. The simple HF method is not suitable because it cannot describe spin polarization and electron correlation, which are necessary for

the hyperfine coupling calculations.⁷⁸ MP2 includes electron correlation, but it severely contaminates the spin ($S^2 \neq 0.75$) and generally the calculated HFCCs are not close to the experimental values. In addition, MP2 is less feasible for large molecular systems owing to large central processing unit (CPU) time. The B3LYP method includes a small contribution (20%) of HF exchange and electron correlation. But it also has some drawbacks, for example, as with all DFT methods it suffers from the self-interaction error and needs correction.⁷⁹ It delocalizes spin densities over several DNA bases more than that found experimentally. Even so, the use of the DFT-based B3LYP method is well tested for a large number of organic and inorganic radicals^{65–67} and DNA radicals^{69–77} for HFCC calculations. Also, it is a good choice for a compromise between accuracy and computational feasibility; the computational cost is comparable to the HF method. It should also be noted that a well-defined basis set is also required to accurately compute the isotropic HFCCs (a_{iso}), although satisfactory anisotropic HFCCs (T_{ii}) can be obtained with almost any method and basis set with the condition that the radical structure is reasonably correct. This is important because the experimental structures of radicals are often not available. Considering this aspect, special basis sets known as *EPR-II* and *EPR-III* were developed to compute HFCC by Barone.⁸⁰ These basis sets are especially designed for computing HFCCs by the DFT method, particularly, B3LYP. The *EPR-II* basis set is a double ζ basis set with a single set of polarization functions. *EPR-III* is a triple- ζ basis set including diffuse functions, double d-polarizations, and a single set of f-polarization functions; for details see the Gaussian web site.⁸¹ Recently, Barone and Cimino⁸² calculated HFCCs for a large data set of 200 radicals using B3LYP and PBE0 methods and 6-31G* and a newly devised N07D basis sets. The calculated mean absolute deviation ($\text{MAD} = \sum |a_{\text{calc}} - a_{\text{exp}}|/N$, where a_{calc} and a_{exp} are calculated and experimental isotropic HFCC values and N is the number of data points) for hydrogen and second row elements C, O, N, and F reported in Gauss are 2.1 (H), 3.5 (second row) for B3LYP/6-31G*, 1.9 (H), 3.2 (second row) for B3LYP/*EPR-III*, 4.2 (second row) for B3LYP/TZVP, and 1.9 (H), 2.1 (second row) for PBE0/N07D, respectively.^{82,83} Thus, the use of the B3LYP/6-31G* method is able to treat the

differential spin polarization and thus provides as good a description of the magnetic properties of hydrogen and second row atom couplings as found for other specifically designed basis sets and functionals. The theoretical calculation provides a and $T_{ii} = [T_{xx}, T_{yy}, T_{zz}]$ and the principal values of the diagonalized hyperfine tensor can then be obtained employing (6) by adding $a + T_{ii}$. The calculation also provides the direction cosines for each T_{ii} which rotate the diagonalized T_{ii} to a common axis system that allows for the simulation of the experimental ESR spectrum.

3 ESR AND THEORETICAL STUDIES THAT ELUCIDATE VARIOUS PROPERTIES OF DNA RADICALS WITH SPECIFIC EXAMPLES

3.1 Ground-State Properties of DNA Radicals

3.1.1 Conformation of DNA Radicals

The DNA (or RNA) sugar radicals discussed in Section 1.1 adopt various conformations as defined by the pseudo-rotation cycle.^{72,84–87} Since HFCC values depend on conformation, the identification of sugar radicals solely on the basis of the HFCC can be difficult.^{70–72,88–90} Using B3LYP/6-31G(d,p) method and considering C4'• as an example of a DNA sugar radical, Parr and Wetmore⁷² have shown that the lowest energy conformation for C4'• depends on the model system chosen. A combination of ESR spectral studies and DFT calculations has established that C5'• in an aqueous (D₂O) glass at low temperature shows only one ca. 20 G doublet splitting from the α -hydrogen at C5'. Even though a β -hydrogen is present on C4', the conformation of the C5' radical is such that only a small and unresolved coupling from it is present.^{70,71,88,89} However, for C5'• in 3'-AMP, there are two different pD-dependent conformations in the pD range of circa 6 to circa 9, which lead to different β -couplings from the hydrogen on C4' (Figures 6 and 7, Ref. 70).

In Figure 6, the ESR spectra of C5'• formed via photoexcitation of A^{•+} in glassy (7.5 M LiCl/D₂O) samples of 3'-AMP at various pDs are shown. The spectrum in Figure 6a obtained at pD circa 6 was assigned to C5'•; the lineshape, center of the spectrum, and the total breadth of this spectrum

Figure 6 Spectra, attributed to $C5'^{\bullet}$, obtained after illumination of one-electron oxidized 3'-AMP in 7.5 M LiCl/D₂O glass at pD 6, 7, and 9. The spectrum from any remaining $A^{\bullet+}$ has been subtracted from each spectrum. $C5'^{\bullet}$ changes its conformation with increasing pD resulting in an increase in the β -hydrogen coupling to the $C4'$ -H atom, as indicated by an increase in the intensity of the line components in the wings of the spectra. The simulated spectrum in C (red) uses the principal hyperfine values: $1\alpha H$ (−9.0, −33.0, and −15.0) G, $1\beta H$ (34.5, 34.5, and 34.5). The g -value principal values used are 2.0032, 2.0049, and 2.0020, and a 4.5 G linewidth with a mixed Lorentzian/Gaussian (1/1) lineshape is also used. [Reprinted with permission from Ref. 70. Copyright 2008 American Chemical Society.]

agrees very well with the reported $C5'^{\bullet}$ spectrum from dGuo,⁸⁸ 3'-dGMP,⁸⁸ dAdo,⁸⁹ 3'-dAMP,⁸⁹ and Guo.⁷¹ The principal feature of this spectrum is a ca. 19 to 21 G anisotropic doublet from the α -hydrogen on $C5'$. A large increase in the isotropic hyperfine coupling from the β -hydrogen on $C4'$ from circa 5 to 34.5 G is observed on increasing the pH from 6 to 9. This can be seen in the wings of the spectra shown; line components arising from the 34.5 G coupling dramatically increase in intensity as the pD increases. At pD circa 7, the spectrum found (6b) is a combination of spectrum a (65%) and spectrum c (35%). Spectrum a (at pD circa 6) has been assigned to the form of the nucleotide that has a HPO_4^- group adjacent to $C3'$ and spectrum c (at pD circa 9) to that with a PO_4^{2-} group (Scheme 7).

The simulated spectrum in 6c (red) employed the following principal values for the hyperfine couplings and g -values: $1\alpha H$ (−9.0, −33.0, −15.0) G; $1\beta H$ (34.5, 34.5, 34.5) G; $g = (2.0032, 2.0049, 2.0020)$. A mixed Lorentzian/Gaussian (1/1) linewidth of 4.5 G was also employed.

Employing B3LYP/6-31G* method, the theoretically calculated value of the isotropic β -hyperfine coupling from the $C4'$ -H atom for the optimized geometry of the higher pD form of 3'-AMP (Figure 7b) was found to be 28.3 G, which is reasonably close to the experimentally obtained value of 34.5 G.⁷⁰

The spectrum found in Figure 6a corresponds to a conformation of the radical site that has a dihedral angle of circa 90° between the z -axis of the singly occupied p_z -orbital on $C5'$ radical and the H- $C4'$ bond. This is equivalent to the dihedral angle $H4'-C4'-C5'-O5'$ equal to 0° (Figure 7a and c). In this particular conformation, the β - $C4'$ proton is in the nodal plane of the $C5'$ radical p_z -orbital and a small hyperfine coupling results (Section 2.1.2). On the other hand, the spectrum in Figure 6c corresponds to a conformation in which the H- $C4'$ bond has a dihedral angle of circa 36° (dihedral angle $H4'-C4'-C5'-O5' = 54^\circ$). In this conformation, a large β - $C4'$ proton hyperfine coupling is found (Figure 7b).⁷⁰ The $C5'$ - αH hyperfine coupling (−21 G), which is found both theoretically and experimentally for both

Figure 7 B3LYP/6-31G* optimized geometries of C5'• in 3'-AMP. (a) Mono-protonated phosphate (PO_4H^-) in the presence of four waters and (b) deprotonated form (PO_4^{2-}) in the presence of three waters. The atoms O5', C5', H5', and C4' are constrained in the same plane in (a) and (b). In (a), the dihedral angle $\text{H4}'\text{--C4}'\text{--C5}'\text{--O5}'$ was constrained to 0° , whereas in (b), it is 54° . (c) and (d) are the exposed views of the atoms O5', C5', H5', and C4' shown in (a) and (b). (c) shows that the C4'–H atom in (a) is in the nodal plane of the p-orbital of C5' radical, whereas (d) points out that it is lifted significantly out of the nodal plane and results in a large β -proton hyperfine coupling from the C4'–H atom in the C5'•. [Reprinted with permission from Ref. 70. Copyright 2008 American Chemical Society.]

Scheme 7 Structure of C5'• in 3'-AMP at low and high pH/pD. The optimized geometries and resulting conformations of these two forms of C5'• are shown in Figure 7.

conformations, is consistent with a C5' radical site in a near-planar conformation.⁹¹

The increase in the C4'β-proton hyperfine coupling with increasing pH is associated with the deprotonation of the phosphate group at $\text{pH} > 7$. This allows for subsequent hydrogen bonding of the C3'–OH to a negatively charged phosphate oxygen

(Figure 7b). As indicated by the fit of the simulated spectrum with experiment in Figure 6c, the hyperfine couplings suggested by theory match nicely with experiment and strongly support the theoretical structure shown in Figure 7b.

3.1.2 Effect of Solvation (Hydration) on DNA Radicals

DNA solvation is fundamentally important to its biological processes that take place in an aqueous environment. It is well known that DNA base cation radicals become more acidic and anion radicals more basic in nature than their corresponding neutral bases.^{7,28} As a result of this enhanced acidic or basic character, DNA cation radicals tend to deprotonate to nearby proton acceptors and the DNA anion radicals tend to protonate from proton donors, for example, from the complementary base in the base pair or the surrounding solvent. These proton transfer processes lead to more stable radicals and

tend to slow or stop hole and electron transfer from base to base. In recent works,^{31,35,69,70,72–75} it was found that when solvation was considered, the experimental properties of DNA ion radicals were well modeled by theory. For example, the HFCCs of G^{+} in monomers,⁶⁹ intra-base pair proton transfer in the ground state of one-electron oxidized $G:C$,³¹ and sugar radical formation by a PCHT in G^{+} in dGuo³⁵ were all nicely described by DFT calculations taking into account the effect of solvation. In theoretical calculations, the effect of solvation is incorporated either by considering the effect of full solvation through the polarized continuum model (PCM) or by placing a number of water molecules around the solute.⁶⁹ From computational points of view, PCM is simple and represents the effect of the bulk solvent; however, PCM lacks the contribution of the solute–solvent interaction, which is established through specific hydrogen bonding interactions. The inclusion of explicit water molecules describes these solute–solvent interactions better, though it is computationally more expensive than the PCM model. The best approach is to include the first few waters and to use the PCM model on the entire system so that both the local and bulk solvation effects are taken into account.

3.1.3 Protonation States of One-Electron Oxidized Guanine in Monomers

Employing ESR and UV–Vis spectroscopy, the deprotonation reactions of G^{+} in dGuo in aqueous medium at low temperatures have been elucidated.⁶⁹ The presence of specific protonation states

of one-electron oxidized guanine in dGuo were observed: (i) guanine cation radical (G^{+}) was found at pH range 3–5, (ii) the singly deprotonated species $G(N1-H)^{\bullet}$ was found in the pH range 7–9, and (iii) doubly deprotonated species $G(-2H)^{-\bullet}$ was shown to be present at $pH \geq 11$. Through ^{15}N substitution at specific nitrogen atoms (N1, N2, and N3), and deuterium substitution at the C8–H atom in the guanine moiety in dGuo, the nitrogen HFCCs were specifically assigned to each of the labeled nitrogen atoms in dGuo.⁶⁹

Using the B3LYP/6-31G* method, the geometries of G^{+} , $G(N1-H)^{\bullet}$, $G(N2-H)^{\bullet}$ (syn- and anti-conformations), and $G(-2H)^{-\bullet}$ in dGuo were fully optimized in the gas phase and in the presence of a single water molecule. The calculation predicted $G(N1-H)^{\bullet}$ to be less stable than the $G(N2-H)^{\bullet}$ by $\sim 3 \text{ kcal mol}^{-1}$.⁶⁹ Although the calculation predicted $G(N2-H)^{\bullet}$ to be more stable, the calculated HFCCs did not match with the experimental ESR HFCCs.⁶⁹ To resolve this problem, the complete first layer of hydration around G^{+} , $G(N1-H)^{\bullet}$, and $G(N2-H)^{\bullet}$ was modeled by placing seven waters in the preferred hydrogen bonding arrangement, fully optimizing the geometries, and calculating the HFCCs using the B3LYP/6-31G* method (for details see Ref. 69). The calculation predicted that $G(N1-H)^{\bullet} + 7H_2O$ was more stable than $G(N2-H)^{\bullet} + 7H_2O$ by $\sim 3 \text{ kcal mol}^{-1}$. Also, the calculated HFCCs for $G^{+} + 7H_2O$ and those for $G(N1-H)^{\bullet} + 7H_2O$ matched very well the experimental HFCC values (Table 1). For $G(-2H)^{-\bullet}$, 8–10 waters were needed to obtain a good agreement between theoretically predicted HFCC values and those obtained from experiment.⁶⁹

Table 1 Experimental and theoretical ESR HFCCs for $G(-H)^{\bullet}$ in Gauss (see Ref. 69 for details). The optimized geometry of $G(-H)^{\bullet}$ with seven water molecules is also shown along with the numbering scheme for $G(N1-H)^{\bullet}$.

	8-D-dGuo/dGuo			dGuo					
	$^{14}N3$ Couplings (G)			$^{14}N2$ Couplings (G)			C8(H) Coupling (G)		
	A_{zz}	A_{xx}	A_{yy}	A_{zz}	A_{xx}	A_{yy}	A_{zz}	A_{xx}	A_{yy}
Exp.	12.0	~ 0	~ 0	8.0	~ 0	~ 0	–7.2	–10.5	–3.5
Theory									
$G(N1-H)^{\bullet} + 7H_2O$	13.5	0.8	0.9	9.1	0.6	0.7	–8.4	–11.3	–3.0
$G(N2-H)^{\bullet} + 7H_2O$	15.0	1.0	1.0	17.6	0.8	0.8	–6.6	–8.8	–2.3

The site of deprotonation of $G^{+\bullet}$ in monomers had been proposed in previous studies to be either from N1 or from N2 nitrogen sites.^{7, 10–16, 18–20, 69} A more recent study using a combination of experiment and theory has led to the identification of the preferred site of deprotonation in dGuo.⁶⁹ This study predicts that even at low temperature, the N1–H site is the preferred site for deprotonation of $G^{+\bullet}$ in monomers. In a gas phase calculation of the conversion of $G(N2-H)^{\bullet}$ to $G(N1-H)^{\bullet}$ employing the B3LYP/6-31G* method and a single water molecule, a substantial barrier (~ 19 kcal mol⁻¹) is obtained.⁶⁹ In an experimental pulse radiolysis investigation, in aqueous solution at ambient temperature, a much lower activation energy for the conversion of $G(N2-H)^{\bullet}$ to $G(N1-H)^{\bullet}$ of 5.5 kcal mol⁻¹, was reported.⁹² The difference between the theoretical and experimental values of the activation barrier clearly points out that full solvation needs to be employed to obtain a reasonable theoretical value of the activation barrier (Section 3.1.2).

3.1.4 Intra-Base Pair Proton Transfer in One-Electron Oxidized G : C

The intra-base pair proton transfer between N1 of G to N3 of C in the G : C cation radical ($C : G^{+\bullet}$)

has been of considerable interest as this reaction is important with regard to hole transfer and reactions of the cation radical.^{7, 12, 25–27} Selective deuteration at C8 in the guanine moiety was employed to study this process. One-electron oxidation of 8-deutero-dGuo (G^*) led to the ESR spectrum of the cation radical ($G^{+\bullet}$) whose $g_{\perp}$ differs from that of the corresponding deprotonated cation radical ($G^*(N1-H)^{\bullet}$) spectrum.²⁵ Using G^* incorporated into dsDNA oligomers, only the ESR spectrum of $G^*(N1-H)^{\bullet} : C(+H^+)$ was found (Figure 8a and b).²⁵ Thus, it was concluded that on one-electron oxidation of G : C in dsDNA, proton transfer occurs in $C : G^{+\bullet}$ from N1 of guanine to N3 of cytosine. This intra-base pair proton transfer reaction was thoroughly investigated using theoretical methods in the gas phase and was found to be endothermic.^{7, 18–20, 93–96} Recently, this reaction was considered by taking into account the effect of the first hydration shell by including 11 water molecules surrounding the G–C base pair. The zero point energy-corrected reaction energies for proton transfer from $G^{+\bullet}$ (N1) to C(N3) was evaluated using the B3LYP/6-31+G** method. The forward barrier for proton transfer was found to be 1.4 kcal mol⁻¹ and the reaction was found to be exothermic in nature (Figure 8c). The proton-transferred $C(+H^+) : G(N1-H)^{\bullet} + 11H_2O$

Figure 8 (a) ESR spectra of $G^{+\bullet}$ and $G^*(-H)^{\bullet}$ obtained from glassy (7.5 M LiCl in D_2O) samples of G^* ($G^* = 8\text{-D-dGuo}$, 96% D) (3 mg ml^{-1}). [Reprinted with permission from Ref. 25. Copyright 2009 American Chemical Society.] (b) Spectrum of the one-electron oxidized dsDNA oligomer $d[G^*CG^*CG^*CG^*C]_2$ (2 mg ml^{-1}), again with $G^*(-H)^{\bullet}$ from (a) in red superimposed. The match of green and red spectra in (b) shows that one-electron oxidized guanine in dsDNA oligomer $d[G^*CG^*CG^*CG^*C]_2$ exists as $G^*(-H)^{\bullet}$. Consult Ref. 25 for details. [Reprinted with permission from Ref. 25. Copyright 2009 American Chemical Society.] (c) The B3LYP/6-31+G** calculated potential energy surface (PES) of proton transfer (PT) in $C : G^{+\bullet}$ in the presence of 11 waters with zero point energy (ZPE) correction. Energy is given in kcal mol⁻¹. Spin density distributions during proton transfer are also shown. [Reprinted with permission from Ref. 31. Copyright 2009 American Chemical Society.]

was found to be $1.2 \text{ kcal mol}^{-1}$ more stable than $\text{C}:\text{G}^{\bullet+} + 11\text{H}_2\text{O}$.³¹

3.1.5 Duplex-to-Solvent Proton Transfer from the Exocyclic Amine (N2) of Guanine in One-Electron Oxidized G:C

The prototropic equilibria of one-electron oxidized G:C (Scheme 8) is crucially influenced by the two reversible proton transfer processes: (i) the intra-base pair proton transfer (process 1) and (ii) the proton transfer from the cation radical (parent or intra-base pair proton-transferred form) to the surrounding solvent (processes 2 and 4). The experimental and theoretical efforts outlined in Section 3.1.4 have established that the site of intra-base pair proton transfer in the G:C cation radical ($\text{C}:\text{G}^{\bullet+}$) is from $\text{G}^{\bullet+}(\text{N1})$ to $\text{C}(\text{N3})$.

Employing B3LYP/DZP++ method, the difference between the energies of the optimized geometries of $\text{C}:\text{G}(\text{N1-H})^{\bullet}$ and $\text{C}:\text{G}(\text{N2-H})^{\bullet}$ (Scheme 8) in the gas phase has been calculated to be 1 kcal mol^{-1} .²⁶ On the basis of this theoretical

result, it is suggested that the site of deprotonation of one-electron oxidized guanine in dsDNA to the surrounding water could be either at N2 or at N1 (see Scheme 8) or more likely a mixture of the two.

The authentic N2 deprotonation radical ($\text{C}:\text{G}(\text{N2-H})^{\bullet}$) in one-electron oxidized d[TGCGCGCA]₂ has been characterized using an authentic $\text{G}(\text{N2-H})^{\bullet}$ spectrum obtained from 1-methyl-2'-deoxyguanosine (1-Me-dGuo) (Figure 10).²⁶ The fact that the methyl-substituted compound, 1-Me-dGuo, or its corresponding RNA analog 1-methyl-guanosine (1-Me-Guo) is a good model for the one-electron oxidized guanine is confirmed through theoretical calculations. Using the B3LYP/6-31G* method, it is found that $\text{G}^{\bullet+}$ and 1-Me- $\text{G}^{\bullet+}$ have identical spin density distributions, as do $\text{G}(\text{N2-H})^{\bullet}$ and 1-Me- $\text{G}(\text{N2-H})^{\bullet}$ (Figure 9). In 1-Me-dGuo or 1-Me-Guo, the N1-H atom is replaced by a methyl group and deprotonation occurs *only* from the N2 site as reported in pulse radiolysis studies by Steenken.^{28–30} The UV–Vis spectrum of 1-Me- $\text{G}(\text{N2-H})^{\bullet}$ obtained via pulse radiolysis studies in aqueous solution at ambient temperature^{28–30} is further supported by the ESR

Scheme 8 Schematic representation of prototropic equilibria in the one-electron oxidized G:C. The intra-base pair proton transfer within the one-electron oxidized G:C (process 1) and proton transfer to water either from the N1 atom (process 2) or from the nitrogen atom in the exocyclic amine (N2) of the guanine moiety in the one-electron oxidized G:C (process 4) are shown. The interconversion between $\text{C}:\text{G}(\text{N1-H})^{\bullet}$ and $\text{C}:\text{G}(\text{N2-H})^{\bullet}$ is represented by process 3. Employing the B3LYP/6-31+G** method, the fully optimized geometries of $\text{C}:\text{G}(\text{N1-H})^{\bullet}$ and $\text{C}:\text{G}(\text{N2-H})^{\bullet}$ in the presence of 11 water molecules have been used to calculate the relative stabilities between $\text{C}:\text{G}(\text{N1-H})^{\bullet}$ and $\text{C}:\text{G}(\text{N2-H})^{\bullet}$ and these near identical values are provided in parentheses. Consult Ref. 26 for details. [Adapted from Ref. 26. © 2010, Royal Society of Chemistry.]

Figure 9 Comparisons of spin density distribution of $G^{\bullet+}$ and $1\text{-Me-G}^{\bullet+}$ as well as of $G(\text{N2-H})^\bullet$ and $1\text{-Me-G}(\text{N2-H})^\bullet$ calculated using B3LYP/6-31G* method for guanine (G) and 1-methyl-guanine (1-Me-G).

Figure 10 (a) ESR spectra of authentic $1\text{-Me-dG}(\text{N2-H})^\bullet$ obtained from glassy (7.5 M LiCl) in D_2O (blue) and in H_2O (green) samples of 1-Me-dGuo by one-electron oxidation. Expansion of the wings by factor of 5 shows the A_{zz} component of the N2-H coupling in H_2O —which is lost in D_2O . (b) Comparison of the spectrum of one-electron oxidized $\text{d}[\text{TGCGCGCA}]_2$ in D_2O from (a) (blue) with that found in H_2O (green) for an otherwise identical sample. Similar to the spectra (see arrows) shown in (a), the A_{zz} component of the remaining N2-H proton hyperfine coupling of $G(\text{N2-H})^\bullet$ is visible (as indicated by the dotted lines in green) in the wing spectrum (green) in (b). All ESR spectra were recorded at 77 K. [Consult Ref. 26 for details.]

and UV–Vis spectroscopic studies of one-electron oxidized 1-Me-dGuo or 1-Me-Guo in glassy systems at low temperatures.²⁶

In Figure 10a, the ESR spectrum of $1\text{-Me-dG}(\text{N2-H})^\bullet$ (green) formed via one-electron oxidation by $\text{Cl}_2^{\bullet-}$ of 1-Me-dGuo in 7.5 M LiCl (H_2O) is shown. For comparison, the ESR spectrum of $1\text{-Me-G}(\text{N2-H})^\bullet$ in D_2O (7.5 M LiCl) (blue) has been superimposed on it. The expanded wings in Figure 10a show the 8 G A_{zz} hyperfine coupling

of the N2-H proton of $1\text{-Me-G}(\text{N2-H})^\bullet$ in H_2O (green), which is lost in D_2O glasses (blue). In Figure 10b, we have compared the spectrum of the one-electron oxidized $\text{d}[\text{TGCGCGCA}]_2$ (green) obtained in H_2O glass with the spectrum of the one-electron oxidized $\text{d}[\text{TGCGCGCA}]_2$ found in D_2O glass (blue). Comparison of Figure 10a and b establishes that one-electron oxidized $\text{d}[\text{TGCGCGCA}]_2$ (green) in H_2O also shows the A_{zz} component of hyperfine coupling of the

exchangeable N-H atom in d[TGCGCGCA]₂. Thus, the G(N2-H)[•] spectrum in one-electron oxidized d[TGCGCGCA]₂ has been identified. Moreover, analyses using authentic G(N1-H)[•] and G(N2-H)[•] spectra show that the radical cohort in spectrum B (either in H₂O or in D₂O) is an equilibrium mixture of C:G(N2-H)[•] (circa 60%) and C:G(N1-H)[•] (circa 40%)—which is expected from the near identical stabilities of these radicals obtained by DFT calculations (Scheme 8).

3.2 Excited-State Processes

The ground states of a variety of DNA radicals (Section 1.1) have been well characterized experimentally and theoretically (Section 3.1). However, very little is known about the excited-state properties of DNA radicals. Excited states are copiously produced as ionizing radiation interacts with DNA.^{10–16,18–20} For radiations with low linear energy transfer (LET), excited states are usually isolated and rapidly deactivate, so they likely result in a small extent of DNA damage. On the other hand, high LET radiations produce dense ionization tracks that have excitations and ionizations in proximity in the core of the track.^{10–16} With this in mind, the fact that irradiation of DNA by a high-energy argon ion beam produces a large number of sugar radicals along the ion-track has led to the suggestion that fast deprotonation from excited-state cation radicals lead to the formation of neutral sugar radicals.⁹⁷ To test this hypothesis, ESR spectral studies of photoexcited one-electron oxidized purines in DNA and RNA model systems (nucleosides, nucleotides, and oligomers) as well as one-electron oxidized highly polymerized dsDNA (salmon sperm) were carried out and formation of sugar radicals was observed.^{12,27} Subsequently, time-dependent (TD)-DFT calculations were carried out to support these experimental results.^{18,19,35,36}

3.2.1 Hole Transfer Processes and Sugar Radical Formation

As shown in Scheme 4, a deoxyribose sugar cation radical once produced rapidly deprotonates, resulting in the formation of a neutral sugar radical such as C1'[•], C3'[•], or C5'[•].¹² Deprotonation is expected to

be especially rapid (< ps range) in an excited state; hence, formation of a neutral sugar radical should readily occur.¹² Employing UV–Vis illumination at 77 K as a means of inducing excited states in trapped G^{•+} in highly polymerized dsDNA (salmon sperm), ESR studies showed that C1'[•] was indeed formed from excited G^{•+}.⁸⁸ Furthermore, in dsDNA, formation of C1'[•] was found to depend on the wavelength of the light used for photoexcitation. In the wavelength range 310–480 nm, C1'[•] formation was observed; at wavelengths ≥ 520 nm, no sugar radical formation was observed (Figure 11).⁸⁸

Further experiments (at 77 and 143 K) in a variety of model DNA and RNA purine mononucleosides, nucleotides, and a variety of ss and ds oligonucleotides showed formation of sugar radicals (C1'[•] and C5'[•]) via excitation of previously trapped purine

Figure 11 (a) ESR spectrum of DNA ice samples (50 mg ml⁻¹ D₂O) γ -irradiated to 15.4 kGy dose, annealed to 130 K to eliminate [•]OH. (b) After illumination at 77 K for 1 h with light >310 nm. (c) After illumination of an identically prepared sample as in (a), at 521 nm for 30 min. (d) Isotropic simulation of spectrum of C1'[•] using the parameters (15 G (1 β H), 37 G (1 β H), 5 G linewidth, and g (2.0029, 2.0029, 2.0029)). This spectrum matches line components in spectrum (b). Consult Ref. 88 for details. [Reprinted from Ref. 88. © 2005, Oxford University Press.]

Scheme 9 Experimental $^{13}\text{C}5'$ HFCC values for $\text{C}5'^{\bullet}$ and DFT calculated $^{13}\text{C}5'$ HFCC values and structures for $\text{C}5'^{\bullet}$ and for $\text{C}4'^{\bullet}$ in dAdo. [Reprinted from Ref. 89. © 2006, Oxford University Press.]

cation radicals.^{27,70,71,88,89,98,99} Observable formation of $\text{C}3'^{\bullet}$ was found in nucleosides with circa 15–35% conversion of the purine cation radical to $\text{C}3'^{\bullet}$.^{70,71,88,89} However, the formation of $\text{C}3'^{\bullet}$ via photoexcitation of $\text{G}^{+\bullet}$ in the dinucleoside phosphate TpdG was found to be small (circa 10%)⁹⁸, decreases substantially (circa $\leq 10\%$) in ssDNA oligomers (e.g., TGT, TGGT, and TGGGT)^{27,98}, and has not been observed in ds oligomers.²⁷

Specific sugar radicals were identified and their hyperfine couplings were characterized by employing nucleosides having isotopic substitutions at specific sites in the sugar moiety, for example, deuterium substitution at $\text{C}3'$ and $\text{C}5'$ sites in dGuo,⁸⁸ at $\text{C}1'$, $\text{C}2'$, $\text{C}3'$, and $\text{C}5'$ sites in Guo,⁷¹ at $\text{C}1'$, $\text{C}2'$, and $\text{C}5'$ sites in Ado, and at the $\text{C}5'$ site in 5'-AMP.⁷⁰ ^{13}C isotopic substitution at the $\text{C}5'$ site in dAdo has led to the unequivocal identification of $\text{C}5'^{\bullet}$.⁸⁹ To determine whether the prominent doublet (circa 19–21 G) observed in sugar radical cohorts (e.g., Figure 6a) was due to $\text{C}5'^{\bullet}$ or $\text{C}4'^{\bullet}$, ^{13}C isotopic substitution at the $\text{C}5'$ site in dAdo was employed.⁸⁹ B3LYP/6-31G(d) fully optimized geometries indicated that the ^{13}C hyperfine couplings at $\text{C}5'$ in $\text{C}5'^{\bullet}$ differ substantially from the corresponding ^{13}C hyperfine couplings at $\text{C}5'$ in $\text{C}4'^{\bullet}$ (Scheme 9). The comparison of experimental and calculated values clearly pointed out that the prominent doublet originated with $\text{C}5'^{\bullet}$ rather than $\text{C}4'^{\bullet}$.

With the aid of the ESR spectral data obtained from selectively isotopically substituted model compounds, a benchmark spectrum of each sugar radical ($\text{C}1'^{\bullet}$, $\text{C}3'^{\bullet}$, and $\text{C}5'^{\bullet}$) was constructed and these were employed to analyze the experimental spectra of the sugar radical cohort found in various DNA and RNA systems. Analyses showed that *no* observable formation of either $\text{C}4'^{\bullet}$ or $\text{C}2'^{\bullet}$ was found via photoexcitation of purine cation radical in DNA and

RNA model systems (monomers to oligomers) and in highly polymerized dsDNA.^{12,27,70,71,88,89,98,99}

The type and yield of various sugar radicals (i.e., $\text{C}1'^{\bullet}$, $\text{C}3'^{\bullet}$, and $\text{C}5'^{\bullet}$) are crucially influenced by various factors: (i) site of phosphate substitution (at $3'$ or $5'$), (ii) pH (i.e., the protonation state of the purine cation radical), (iii) wavelength or the excitation energy, (iv) temperature during photoexcitation, (v) length and sequence of the oligomer, and (vi) type of the oligomer (ss or ds).^{12,27,71} The effects of these factors to the sugar radical formation via excited purine cation radical have recently been reviewed.¹²

Contrary to the wavelength-dependent formation of $\text{C}1'^{\bullet}$ via photoexcitation of $\text{G}^{+\bullet}$ in dsDNA,⁸⁸ the formation of sugar radicals in dGuo, and in ssDNA oligomers with four or fewer bases was not found to be wavelength dependent.^{12,27,98} However, sugar radical formation was found to be wavelength dependent for a longer ssDNA oligomer (10-mer)^{12,27,98} and for dsDNA oligomers.²⁷ The reason for this has been explained with the aid of TD-DFT calculations for excited states of DNA base cation radicals (Figure 12).

In order to understand the mechanism of sugar radical formation due to photoexcitation of cation radical of purines, TD-DFT calculations were performed. In these calculations, the ground-state geometries of $\text{G}^{+\bullet}$ in dGuo and several dinucleoside phosphates (TpdG, dGpdG, dApdA, dApT, TpdA, and dGpT) in their cation radical states were optimized by the B3LYP/6-31G* method and their vertical excited states were studied.^{88,99,100} For example, the vertical excited states of $\text{G}^{+\bullet}$ in dGuo were calculated employing the TD-B3LYP/6-31G* method (Figure 12a). In the ground state of $\text{G}^{+\bullet}$ in dGuo, the hole is localized on the guanine base as evident from the plot of the SOMO shown, in direct agreement with the ESR studies.⁸⁸ The TD-DFT calculations

Figure 12 (a) Molecular orbitals and energy level filling diagram for G^{*+} in dGuo. MOs were computed by TD-DFT (6-31G* and B3LYP) and visualized via Gaussview. The SOMO is the expected MO for G^{*+} with the hole localized on the guanine base. A number of inner shell MOs are localized on the sugar ring. [Reprinted from Ref. 88. © 2005, Oxford University Press.] (b) Schematic representation of base-to-base hole transfer, which is favored at longer wavelengths, and base-to-sugar–phosphate hole transfer, which is favored at shorter wavelengths, on photoexcitation of $TpdG^{*+}$. Two of the 20 transitions calculated are shown for the 0.76 and 1.68 eV transitions. The MOs were obtained by employing TD-DFT/B3LYP/6-31G(d) calculations. [Adapted with permission from Ref. 99 Radiation Research, Copyright (2006), Radiation Research Society.]

predict that during excitation, electronic transitions take place from inner MOs to the SOMO, as shown by the arrow thereby showing that, on excitation, the hole transfers from the guanine moiety to the sugar. The sugar cation radical, thus formed in the excited state, deprotonates quickly to produce a neutral sugar radical. These TD-DFT calculations also indicate that the light-induced transitions occur in the whole UV–Vis spectral range (1.5–3.7 eV) from inner MOs to the SOMO, thereby agreeing with the experimental observation (*vide supra*) that sugar radical formation via photoexcitation of G^{*+} in dGuo is wavelength independent.⁸⁸ However, the excited states of dinucleoside phosphates gave a different result.^{99,100} The lowest transition for all the dinucleoside phosphates showed *base-to-base* hole transfer and higher transitions showed the *base-to-sugar* hole transfer (Figure 12b). This provided the explanation for the observation that DNA

sugar radicals were not formed at wavelengths >520 nm.

3.2.2 DNA Damage via Low-Energy Electrons

Secondary electrons formed by ionizing radiation lose their kinetic energy and after thermalization are captured by the bases in DNA.^{10–16,21} Electron transfer thereafter results in the formation of the thymine and cytosine anion radicals (Scheme 5). Secondary electrons having significant kinetic energy before thermalization can lead to DNA damage. Such electrons with kinetic energies between 0 and 20 eV are known as LEEs.^{37,101,102} Recently, LEEs have been recognized to cause single- and double-strand breaks (SSB and DSB) in plasmid DNA through a DEA mechanism.^{37,103,104}

Scheme 10 Schematic diagram showing the formation of SSB due to attachment of LEE to a thymidine moiety in DNA. Paths A and B show the two possible paths for the SSB. The percentage of each path is determined by the relative concentrations of $C3'_{\text{dephos}}^{\bullet}$ and $ROPO_2^{\bullet-}$. In theoretical calculations (Refs 106–112), one of the oxygen atoms of the phosphate group is protonated to neutralize the charge of the phosphate group.

LEEs have been proposed to account for two of the free radicals produced in $^{16}\text{O}^{8+}$ ion beam-irradiated hydrated DNA.¹⁰⁵ From ESR measurements, a new phosphorus-centered radical species was identified by its large ^{31}P parallel hyperfine coupling of circa 775 G as a phosphoryl radical ($ROPO_2^{\bullet-}$). This radical was proposed to be produced by the dissociation of P–O bond through DEA (path B, Scheme 10).¹⁰⁵ In other experiments, hydrated DNA samples at 77 K were irradiated with argon ion beams (^{36}Ar or ^{40}Ar having energies between 60 and 100 MeV/nucleon).⁹⁷ The ESR spectra of these samples indicated the presence of a radical with an unusually large number of hydrogen hyperfine couplings. A variety of considerations led to the conclusion that this was the dephosphorylated $C3'$ radical ($C3'_{\text{dephos}}^{\bullet}$ (path A, Scheme 10)) formed by the rupture of the deoxyribose $C3'$ – $O3'$ bond.⁹⁷ The formation of these two radicals was proposed to be the result of LEE-induced formation of a transient negative ion (TNI) that resulted in bond cleavage in the DNA–sugar–phosphate backbone as shown in Scheme 10.

Employing 3'-thymidine monophosphate (3'-TMP) as a model for DNA (Scheme 10), two alternative paths occur for SSB formation after LEE attachment. At present, there is experimental and theoretical evidence in model systems that the initial capture of the electron may be a “shape” resonance in a π^* state mainly on the DNA base.^{18,19,37} In path A (Scheme 10), C–O bond cleavage at $C3'$ occurs resulting in the formation of $C3'_{\text{dephos}}^{\bullet}$ and a diamagnetic polymeric remnant. In

path B (Scheme 10), a P–O bond is broken, resulting in the formation of $ROPO_2^{\bullet-}$ and a diamagnetic polymeric remnant. The relative amounts of the radicals $C3'_{\text{dephos}}^{\bullet}$ and $ROPO_2^{\bullet-}$ trapped at 77 K, greatly favor $C3'_{\text{dephos}}^{\bullet}$ formation, with circa 95% of the reaction occurring along path A and circa 5% along path B.^{10–12,15,16,97,105} The reactions of LEEs are rather remarkable because the electrons involved have energies lower than the ionization energy of DNA, yet bond cleavage and strand breaks are formed from them. Section 3.2.3 reveals that DFT calculations confirm that these processes can occur through direct resonant processes.

One radical depicted in Scheme 10, $ROPO_2^{\bullet-}$, has a very large hyperfine coupling^{97,105} so that its ESR spectrum is outside the magnetic field range shown in Figure 1. Its ESR spectrum is shown in Figure 13. In this figure, the three Frey salt resonances are shown with three vertical lines in the middle of the spectrum and the full ESR spectrum spans a range of about 1000 G rather than the 250 G shown in Figure 1. The off-scale sections of this spectrum arise from the central DNA spectrum shown in Figure 1, which has a much greater intensity than that of the $ROPO_2^{\bullet-}$ spectrum. The spectrum of $ROPO_2^{\bullet-}$ shown was observed using ^{36}Ar ion beam-irradiated DNA¹⁰²; it is also present in γ -irradiated samples, but at very low concentrations.

It should be noted that $ROPO_2^{\bullet-}$ can originate with P–O bond cleavage at a $C3'$ -phosphate group or at a $C5'$ -phosphate (Scheme 10). ESR investigations of this radical in polymeric DNA samples, which are

Figure 13 ESR spectra of phosphorus-centered radical ($\text{ROPO}_2^{\bullet-}$). (a) Spectrum of DNA hydrated to $\Gamma = 9$ and irradiated with an ^{36}Ar ion beam, 80 MeV/nucleon ($\text{LET} = 650 \text{ keV}/\mu\text{m}$), with a dose of 170 kGy at 77 K. The spectrum of a phosphoryl radical, $\text{ROPO}_2^{\bullet-}$, is evident in the wings. (b) Simulated spectrum of $\text{ROPO}_2^{\bullet-}$ ($A_{zz} = A_{||} = 775 \text{ G}$, $A_{yy} = A_{xx} = A_{\perp} = 610 \text{ G}$, $g_{xx} = g_{||} = 2.00$, $g_{yy} = g_{zz} = g_{\perp} = 2.01$ and a Gaussian line shape with linewidth 12 G). The spectrum is calculated to second order because of the large phosphorus hyperfine coupling constants involved. [Adapted with permission from Ref. 97 Radiation Research, Copyright (2003) Radiation Research Society.]

amorphous, cannot distinguish between these two sites. The presence of both $\text{C3}'_{\text{dephos}}^{\bullet-}$ and $\text{ROPO}_2^{\bullet-}$ supports the role of LEE in these processes.

Recent theoretical efforts (Section 3.2.3) have shown that LEE addition to DNA may effectively create an anion excited state (TNI, Scheme 10) by addition to a unoccupied MO of higher energy^{18,19,111,112} than the LUMO.^{106,107}

3.2.3 Theoretical Studies of DNA Damage via Low-Energy Electrons

Using TD-DFT calculations, three types of mechanisms were proposed in the literature for

LEE-induced strand break formation: (i) LEE attachment to the lowest energy π^* MO of the base followed by transfer to dissociative σ^* MOs on the sugar phosphate group, resulting in rupture of the C–O bond,^{106,107} (ii) direct addition of LEE to the sugar–phosphate backbone of DNA to create the strand break,^{108,109} and (iii) LEE-induced formation of the various shape resonances producing a TNI that leads to strand breaks^{110–112} (Scheme 10). The TNI is formed when an electron is vertically attached to a neutral molecule without changing its neutral ground-state geometry, as shown in Scheme 10. Mechanisms (i) and (ii) are specific examples of the more general mechanism (iii).

It is well known that during LEE–molecule interactions, shape resonances effectively produce transient excited states of the incipient anion radical.¹¹¹ Thus, a fruitful understanding of the SSB formation in DNA can be obtained from the study of the excited states of the TNI (TNI^*). Hence, the excited states of the anion radical of 5'-TMP (as a model of DNA) were investigated using TD-DFT.¹¹¹ The geometries of 5'-TMPH in their neutral state were fully optimized using the B3LYP/6-31G* method. The lowest three excited states of the TNI were calculated using the TD-BHandHLYP/6-31G* method. In this study, the ground and three lowest excited-state potential energy surfaces were generated as the C5'–O5' bond length was increased in 0.1 Å increments, and at each fixed C5'–O5' bond length, the vertical excited states of the TNI were calculated (Figure 14). The three lowest calculated transition energies of the TNI were found to be $\pi(\text{T}) \rightarrow \sigma(\text{PO}_4)^*$, $\pi(\text{T}) \rightarrow \pi(\text{T})^*$, and $\pi(\text{T}) \rightarrow \sigma(\text{S})^*$ in nature and have transition energies 1.42, 1.68, and 2.06 eV, respectively. The calculated 1.68 eV transition is in good agreement with those obtained from electron transmission spectroscopy experiments of thymine.¹¹³ From Figure 14, we see that the ground-state anion radical surface (lowest surface) is a π -type ground state and has a barrier height of circa 18.7 kcal mol⁻¹ at 1.7 Å for the C–O bond cleavage. This makes the first mechanism (i) suggested above unlikely as the barrier height is substantial. The second and third excited-state surfaces corresponding to $\pi(\text{T}) \rightarrow \pi(\text{T})^*$ and $\pi(\text{T}) \rightarrow \sigma(\text{S})^*$ transitions also exhibit a bound-state character. However, the first ($\pi(\text{T}) \rightarrow \sigma(\text{PO}_4)^*$) surface shows a dissociative nature. Such a dissociative nature for the $\pi \rightarrow \sigma^*$ transitions in excited states are well documented in the literature.¹¹¹ The presence of the

Figure 14 Lower curve: Potential energy surface (PES) of the 5'-TMPH transient negative ion (TNI); calculated in the neutral optimized geometry of 5'-TMPH with C5'-O5' bond elongation. SOMO is shown at selected points. Upper curves: calculated vertical excitation energies of the radical anion at each point along the PES, MOs involved in excitations are also shown. Energies and distances are given in eV and Å, respectively. The lowest $\pi\pi^*$ state (triangles) and lowest $\pi\sigma^*$ states (square) are shown. [Reprinted with permission from Ref. 111. Copyright 2008 American Chemical Society.]

$\pi(T) \rightarrow \sigma(PO_4)^*$ transition at <2 eV clearly indicates that LEEs with this energy can directly attach to the sugar-phosphate group during TNI formation and result in a prompt SSB formation in DNA.

4 CONCLUSION

This article describes work that combines the utility of ESR spectroscopy with modern computational chemistry methods such as DFT to elucidate free radical processes in irradiated DNA systems at low temperatures. DFT calculations aid in the identification of DNA base and sugar-phosphate radicals by prediction of stabilization energies, conformations, and most importantly for ESR, predicting accurate values of the HFCCs. ESR spectral studies carried out by employing isotopic substitution (D, ^{13}C , and ^{15}N) at selective sites in the DNA (or RNA) base,^{25,69} in the DNA (or RNA) sugar moiety,^{70,71,88,89} as well as in the solvent (H_2O^{17} in place of H_2O^{16})³³ have made substantial contributions toward identification of these radicals by characterization of the sites having major hyperfine couplings. The powerful combination of ESR spectral studies and DFT calculations is found to clarify various properties of DNA radicals, which are important to the biological consequences of radiation damage.

These include likely sites of deprotonation in the base cation radical, intra-base pair proton transfer processes, excited-state reactions, and many others. In the future, increasing computational power along with advances in DFT methods, combined with corresponding improvements in ESR spectroscopy, such as high field spectroscopy,¹¹⁴ double resonance,²⁰ and pulse techniques¹¹⁵ will answer still more interesting questions about radiation-produced DNA radicals.

Radical-Based Damage of Sulfur-Containing Amino Acid Residues

Christian Schöneich

Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS, USA

1 INTRODUCTION

Sulfur (S)- and selenium (Se)-containing amino acids serve a variety of important functions in peptides and proteins such as the maintenance of structure (e.g., through disulfide bonds),¹ the binding of metals,² as sites for redox regulation³ or mediators of redox processes,⁴ as target sites for electrophiles,⁵ and as constituents of active sites. Inherent to S- and Se-containing amino acids is their efficient reaction with free radicals and reactive oxygen species, which may lead to conformational changes and/or both activation and inactivation of enzymes dependent on the extent of modification and the nature and location of the reaction products. Such radical- and/or oxidation/reduction-based modifications are of significance for an increasing number of cellular signal transduction processes^{3,5} and also for protein damage, which is frequently observed under biologic conditions of oxidative stress (see **Oxidative Damage to Proteins**).⁶ Importantly, a radical reaction with a primary target amino acid will lead to secondary radicals. These may engage in radical- and/or electron-transfer processes with additional protein amino acids such that the ultimate location of a radical damage may evolve potentially far from the site of initial radical attack. Such processes have been documented for radicals derived from S-containing amino acids.⁷ Hence, the reaction of radicals with S- and Se-containing amino acids has the potential for

generating a wide array of reaction products and a thorough understanding of such processes would ultimately be of great benefit for biomedical studies attempting to correlate the oxidative damage of specific proteins under conditions of oxidative stress with physiologic observations. For this purpose, this article will cover both the reactions of free radicals with S- and Se-containing amino acids and the radical chemistry of the product radicals from these amino acids. The scope of reactions has mostly been limited to radicals of biological relevance.

This article focuses predominantly on radical reactions of specific S- and Se-containing amino acids important for mammalian proteins and physiology, which are introduced in the following (the respective structures are displayed in Figure 1). In native mammalian proteins, S- and Se-containing L-amino acids are present as cysteine (Cys, **1**), selenocysteine (SeCys, **2**), methionine (Met, **3**), and selenomethionine (SeMet, **4**), where the number of SeCys- and SeMet-containing proteins is very small relative to the total number of proteins.⁸ Cys is also key to the activity of the tripeptide glutathione (GSH, **5**), which is present in tissue at concentrations up to millimolar range. The amino acid homocysteine (Hcys, **6**) does not represent a building block of proteins, but can bind to proteins through the formation of mixed disulfides or reaction of its thiolactone form with protein nucleophiles.^{9,10} Hcys can form through a free radical reaction of Met¹¹

(*vide infra*). Hcys displays pro-inflammatory activity and its physiologic levels represent an important risk factor for several pathologies, including cardiovascular disease and stroke.^{9,12}

2 THIOLS AND SELENOLS

On the basis of the relatively low bond dissociation energies (BDEs) of RS-H (BDE = 367 kJ mol⁻¹¹³) and RSe-H (BDE = 310 kJ mol⁻¹¹⁴), thiols and selenols are excellent hydrogen donors for hydrogen transfer reactions to radicals. These reactions generate thiyl (X=S) and selenyl (X=Se) radicals, respectively (reaction 1):

Rate constants for such hydrogen transfer processes depend on the nature of the radical Y[•] and, representatively measured for RXH = dithiothreitol (DTT), can be as low as 7.4 × 10⁷ M⁻¹ s⁻¹ for Y[•] = [•]CH₃¹⁵ or as high as 1.4 × 10¹⁰ M⁻¹ s⁻¹ for Y[•] = HO[•].¹⁶ The reaction of heteroatom (Z)-substituted carbon-centered radicals from alcohols, ethers, and amines with thiols is reversible¹⁷⁻²¹ (equilibrium 2; for more details on such reversible reactions of Cys, Hcys, and GSH, *vide infra*):

For synthetic organic reactions, the reverse reactions, that is, hydrogen transfer from C-H bonds to thiyl radicals, have been explored in epimerization processes, and thiols have been referred to as “polarity reversal catalysts.”²² Thiyl radicals also play an important role in enzymatic processes such as that catalyzed by the ribonucleotide reductases,²³⁻²⁵ pyruvate formate lyase,^{23,25-28} benzylsuccinate synthase,^{29,30} and glycerol dehydratase.³¹ Here, intermediary Cys thiyl radicals abstract hydrogen atoms from substrate during the catalytic cycle of ribonucleotide reductase, benzylsuccinate synthase, and glycerol dehydratase, while in pyruvate formate lyase, an intermediary Cys thiyl radical adds to the carbonyl group of the substrate pyruvate (see **Radical Enzymes**).

2.1 Cysteine, Homocysteine, and Glutathione

2.1.1 Formation and Properties of Thiyl Radicals

The mercapto group of the free amino acids Cys and Hcys ionizes with pK_a values of 8.15 and 8.7,³² respectively (measured at 30 °C, μ = 0.3) (isothermal titration microcalorimetry of Cys confirms a thiol pK_a of 8.22 ± 0.16³³), while the thiol pK_a of GSH is 8.93 ± 0.04 (at 25 °C).³⁴ A significantly wider pK_a range is observed for protein Cys residues, which display pK_a values as low as 5³⁵ and as high as ca. 10.75.³³ Thiol ionization has a profound effect on the reaction of thiol/thiolate with free radicals as well as the potential stabilization of thiyl radicals. For example, nonoxidizing carbon-centered radicals react preferentially with the protonated thiol form (reaction 1), while oxidizing radicals prefer reaction with the deprotonated, thiolate form (reaction 3).³⁶:

The resulting thiyl radicals associate with a second, nonoxidized thiolate to produce a 2σ/1σ* three-electron-bonded disulfide radical anion [RS : SR]⁻ (equilibrium 4).³⁷:

Equilibrium constants for thiyl radical/thiolate complex formation (equilibrium 4) have been measured for Cys and Hcys and are of the order of 706 and 600 M⁻¹, respectively.³⁸ In contrast, intermolecular complexes between thiyl radical and protonated thiol display low stability and either dissociate (reaction 5) or eliminate a proton to yield the disulfide radical anion (equilibrium 6):

This situation can change for proteins, where Cys residues may stay in close contact through conformational restrictions. In fact, both the disulfide radical anion and its protonated form have been detected on one-electron reduction of bovine IgG

Figure 1 Structures of S- and Se-containing amino acids and GSH.

by $\text{CO}_2^{\cdot-}$ in a pH-dependent manner (reaction 7), and the pK_a for equilibrium (8) in bovine IgG is between 4.5 and 6.5³⁹:

The disulfide radical anion is a strongly reducing species, with $E^0 = -1.60 \text{ V}$ (for the half reaction $\text{e}^- + \text{RSSR} = [\text{RS} \cdot \text{SR}]^-$),⁴⁰ which efficiently reduces molecular oxygen to superoxide (reaction 9).⁴¹ In contrast, thiyl radicals are oxidizing species with $E^0 = 1.33 \text{ V}$ for the half reaction $\text{RS}^\cdot + \text{e}^- + \text{H}^+ = \text{RSH}$ (determined for 2-mercaptoethanol)⁴⁰ and $E^0 = 0.74 \pm 0.01 \text{ V}$ for the half reaction $\text{RS}^\cdot + \text{e}^- = \text{RS}^-$ ⁴⁰ ($E^0 = 0.73 \text{ V}$ reported for Cys thiyl radicals, $\text{CysS}^\cdot$ ⁴²). More recent electrochemical experiments on the oxidizing power of glutathione thiyl radical ($\text{GS}^\cdot$) reveal $E_m = 0.92 \pm 0.03 \text{ V}$ at pH 7.4⁴³:

Hence, through the association with thiolate, an oxidizing thiyl radical converts into a reducing radical anion, and the net availability of oxidizing and reducing species in a given biologic environment will be a function of thiol concentration and thiol pK_a . Thiyl radicals and disulfide radical anions can be monitored directly with time-resolved UV spectroscopy (coupled to laser flash photolysis or pulse radiolysis), where thiyl radicals have

a reported absorbance maximum at 330 nm with reported absorption coefficients between 100 and $1200 \text{ M}^{-1} \text{ cm}^{-1}$ depending on the nature of the thiyl radical.^{44,45} If experimentally possible, thiyl radicals should be detected complementary also through their disulfide radical anion complexes, which absorb around 420 nm with absorption coefficients of the order of $8000 \text{ M}^{-1} \text{ cm}^{-1}$ ($[\text{RS} \cdot \text{SR}]^-$ from Cys and GSH)⁴⁶ (see **Radiation-Induced Radical Reactions**).

2.1.2 The Reaction of Cys with Carbon-Centered Radicals

The forward reaction of equilibrium (2) represents a hydrogen transfer from a thiol to a carbon-centered radical. Experimental and theoretical data indicate that the kinetics of hydrogen transfer are influenced by polar effects,^{15,47,48} that is, the stabilization of polar transition states through substituents on the carbon-centered radical. For example, experimental values for k_2 increase in the series $\cdot\text{CH}_3 < \cdot\text{CH}_2\text{OH} < \cdot\text{C}(\text{CH}_3)_2\text{OH}$, while the experimental activation energies E_a show the opposite trend.¹⁵ Theoretical calculations (gas phase) reveal decreasing activation enthalpies for the series $\cdot\text{CH}_3 > \cdot\text{CH}_2\text{OH} > \cdot\text{C}(\text{CH}_3)_2\text{OH}$, consistent with the experiment¹⁵ (in equilibrium 2, $\cdot\text{CH}_3$ is represented by $-\text{Z}_n-\text{C}^\cdot$ for which $n = 0$). They also reveal increasing charge separation in the transition state for the series $\cdot\text{CH}_3 < \cdot\text{CH}_2\text{OH} < \cdot\text{C}(\text{CH}_3)_2\text{OH}$,¹⁵ in support of the polar effect already suggested by Roberts and Steel.⁴⁷ Polar transition states can be expressed through a series of valence-bond

Figure 2 Valence-bond structures of transition states for hydrogen transfer reactions. [Adapted from Refs 15 and 47.]

structures **Ia–Id**, where structure **Ic** may be better expressed as three- and one-electron bonded structures **IIa** and **IIb**, respectively, displayed in Figure 2.^{15,47} With reference to equilibrium (2), A in Figure 2 corresponds to RS and B corresponds to $-\text{Z}_n-\text{C}$, that is, for the reaction of hydroxymethyl radicals with a thiol, structures **IIa** and **IIb** would translate into $[\text{RS} \cdot : \text{H}^+ \text{CH}_2\text{OH}]$ and $[\text{RS}^-\text{H} \cdot \text{CH}_2\text{OH}]$, respectively.

Importantly, the oxidizing carbon-centered radical $\cdot\text{CH}_2\text{CHO}$ reacts only very slowly with GSH,³⁶ an observation that can be rationalized by the lack of stabilization of a positive charge on the methylene carbon in the transition state. In fact, oxidizing carbon-centered radicals such as $\cdot\text{CH}_2\text{CHO}$ will react predominantly with thiolate, RS^- .

Values for k_2 and k_{-2} have been obtained through isotope exchange of C–H bonds,^{49–51} radiation chemical isomerization,¹⁷ and time-resolved pulse radiolysis experiments.^{18,19,38} For alcohols and ethers, $k_2 = 10^7\text{--}10^8 \text{ M}^{-1} \text{ s}^{-1}$ and $k_{-2} = 10^3\text{--}10^4 \text{ M}^{-1} \text{ s}^{-1}$,^{17–19} and for amino acids at pH 10.5 (i.e., the anionic form), $k_{-2} = 3.2 \times 10^5 \text{ s}^{-1}$ (Gly) and $7.7 \times 10^5 \text{ s}^{-1}$ (Ala).³⁸ In contrast, for amino acids within model peptide structures such as *N*-acetyl amino acid amides, and for cyclic amino acid anhydrides, diketopiperazines, $k_{-2} = 10^3\text{--}10^5 \text{ M}^{-1} \text{ s}^{-1}$.⁵⁰ An important question is whether reversible hydrogen transfer reactions of $\text{CysS}^\cdot$ proceed *intramolecularly* in peptides and proteins, that is, whether $\text{CysS}^\cdot$ radicals are in equilibrium with other amino acid radicals and are potentially able to initiate the oxidation of other amino acids. For $\text{GS}^\cdot$, an *intramolecular* hydrogen transfer equilibrium between the $\alpha\text{C-H}$ group of the N-terminal $\gamma\text{-Glu}$ residue and $\text{CysS}^\cdot$ radical had been demonstrated through electron

spin resonance and pulse radiolysis experiments (equilibrium 10), where $k_{10} = 1.8 \times 10^5 \text{ s}^{-1}$.^{38,52} This hydrogen transfer is facilitated through deprotonation of the N-terminal amino group of GSH ($\text{p}K_{\text{a,NH}_3^+} = 9.28 \pm 0.1$; 25°C ³⁴) but proceeds well at neutral pH unless thiyl radicals are directed toward competitive pathways such as reaction with thiolate (equilibrium 4) or with oxygen (*vide infra*) (especially in physiological environment also the reaction of thiyl radicals with ascorbate has to be considered):

Analogous hydrogen transfer reactions have been documented for thiyl radicals from Hcys (equilibrium 11) and Cys (equilibrium 12),³⁸ where the rate constants for the forward reactions, $k_{11} = 2.2 \times 10^5 \text{ s}^{-1}$ and $k_{12} = 2.5 \times 10^4 \text{ s}^{-1}$. Reaction (12) represents a 1,3-H-shift, and generally activation energies for 1,3-H-shifts (and 1,2-H-shifts) in radicals are significantly higher than that for 1,4- and 1,5-H-shifts,^{53,54} rationalizing that $k_{12} < k_{11}$:

Theoretical calculations for the gas phase indicate that hydrogen transfer from the γ -Glu α C-H group in GS• to the thiyl radical represents the preferred pathway, associated with a free energy of activation, $\Delta G^\ddagger = 40 \text{ kJ mol}^{-1}$,⁵⁵ though thermodynamically all α C-H bonds in GS• are expected to have a lower BDE compared to the BDE of the S-H bond ($\text{BDE}_{\text{S-H}} \approx 367 \text{ kJ mol}^{-1}$): $\text{BDE}_{\alpha\text{C-H, Gln}} \leq 329 \text{ kJ mol}^{-1}$ for the configuration $\text{H}_2\text{N}-\text{C}^\alpha\text{H(R)}-\text{CO}_2\text{H}$ (experimental value), $\text{BDE}_{\alpha\text{C-H, Cys}} = 346 \text{ kJ mol}^{-1}$,¹³ and $\text{BDE}_{\alpha\text{C-H, Gly}} \leq 350 \text{ kJ mol}^{-1}$. However, recent pulse radiolysis experiments have expanded the range of possible hydrogen transfer reactions of GS•, suggesting, based on time-resolved UV spectroscopy, that not only the α C-H but also the β C-H group of the γ -Glu residue are targets for hydrogen abstraction by the thiyl radical in GS•.⁵⁶ The latter is counter-intuitive based on a comparison of BDEs, where the α C-H bond of the γ -Glu residue (experimental: $\text{BDE} \leq 329 \text{ kJ mol}^{-1}$ for the configuration $\text{H}_2\text{N}-\text{C}^\alpha\text{H(R)}-\text{CO}_2\text{H}$ ⁵⁷) should be considerably lower than the BDE of β C-H (BDE is expected to be of the order of 395 kJ mol^{-1} when compared to the secondary C-H bond in propane⁵⁸). However, clearly the time-resolved experiments by Hofstetter *et al.*⁵⁶ suggest the presence of more than one carbon-centered radical in GS•. Some additional apparent discrepancies between theory and experiment need to be addressed: calculations for Hcys reveal an activation energy for reaction (11) of circa 50 kJ mol^{-1} ⁵⁹; nevertheless, the rate constants for reactions (10) and (11) are comparable, where the experimental value of $k_{11} = 2.2 \times 10^5 \text{ s}^{-1}$ was discussed as possibly being even too low.³⁸ On the other hand, calculations predict a high activation enthalpy for reaction (12), $\Delta H^\ddagger = 83 - 115 \text{ kJ mol}^{-1}$.^{13,55} Nevertheless, a rate constant of $k_{12} = 2.5 \times 10^4 \text{ s}^{-1}$

was reported. Although it was discussed that this value may be too high, the fact remains that reaction (12) was observed for CysS• despite the calculated high activation enthalpy. Calculations also revealed a very high free energy of activation for hydrogen transfer between the Gly residue and the thiyl radical in GS•, $\Delta G^\ddagger = 134 \text{ kJ mol}^{-1}$ for the more stable peptide conformation,⁵⁵ consistent with the original reports of exclusive hydrogen transfer between the γ -Gln α C-H bond and the thiyl radical in GS•. However, pulse radiolysis and laser flash photolysis experiments established rate constants for reversible hydrogen transfer equilibria in radicals from several Cys-, Gly-, and Ala-containing peptides. For example, for radicals from *N*-acetyl-CysGly₆, equilibrium (13) is characterized by rate constants of $k_{13} = 1 \times 10^5 \text{ s}^{-1}$ and $k_{-13} = 8.9 \times 10^5 \text{ s}^{-1}$, that is, $k_{13} \approx 0.1$.⁴⁵

Of course with six available Gly residues in *N*-acetyl-CysGly₆, the possibility exists that hydrogen transfer does not involve the residue at position $n + 1$, but Gly residues further along the model peptide chain. On the other hand, mass spectrometry experiments on products originating from thiyl radicals of several model peptides suggest that CysS• within a model peptide can react via hydrogen transfer with amino acids at the $n + 1$ position.⁶⁰ For example, when the disulfide-containing peptide (GlyGlyCysGlyGlyLeu)₂ was photolyzed with 253.7-nm light in D₂O, both Gly residues in position $n + 1$ and $n - 1$ underwent covalent H/D exchange, analyzed in the final products.⁶⁰ The suggested mechanism for covalent H/D exchange is displayed in the following reactions:

Further evidence for thiol radical-dependent $\alpha\text{C}^\bullet$ radical formation at amino acid residue at positions $n + 1$ and $n - 1$ comes from photochemical studies of the disulfide-bound dimer (LeuGlyAlaCysAlaGlyLeu)₂, where initial thiol radical formation resulted in the conversion of L-Ala into D-Ala.⁶¹ Experimental mass spectrometry studies confirm the potential for CysS $^\bullet$ radicals to abstract hydrogen atoms from amino acid residues at positions $n + 1$ and $n - 1$ in the gas phase.⁶² Under mass spectrometry conditions, the mobile proton model allows for the protonation of the carbonyl functions of various amide bonds, rendering the protonated amides more powerful electron-withdrawing functionalities, which can result in a higher captodative stabilization of some $\alpha\text{C}^\bullet$ radicals. In calculations for solution conditions, Himo⁶³ showed that hydrogen bonds with both amides in the Gly model CHO–NH–CH₂–CO–NH₂ reduced the Gly $\alpha\text{C}^\bullet$ –H bond energy by circa 4.2 kJ mol^{−1}, and solvation also led to a reduction by circa 5.4–8.8 kJ mol^{−1}. However, the effects of hydrogen bonding on the free energy of activation for hydrogen transfer are currently unknown.

2.1.3 The Reaction of Cys with Superoxide

Superoxide anion (O₂ $^{\bullet-}$) represents the initial one-electron reduction product of molecular oxygen, and several enzymatic routes generate superoxide under conditions of oxidative stress. Superoxide serves as a precursor for various reactive oxygen species, most of which react with thiols (e.g.,

peroxynitrite, the product of nitrogen monoxide (NO), and superoxide, or the carbon trioxide radical anion, CO₃ $^{\bullet-}$, which forms via homolysis of ONO₂CO₂ $^-$, a complex of peroxynitrite and CO₂).⁶⁴ A biologically important and controversially discussed question is the *direct* reaction of superoxide with Cys (and thiols, in general). The exposure of various biologically relevant thiols to a superoxide-generating system (xanthine/xanthine oxidase) resulted in a superoxide-dependent, that is, superoxide dismutase (SOD)-inhibitable, loss of these thiols via a short chain reaction, paralleled by the consumption of oxygen.⁶⁵ Importantly, only Cys and penicillamine (Pen) promoted the formation of H₂O₂, while no H₂O₂ formation was detected for cysteamine (Cya), GSH, *N*-acetylcysteine (NAC), and DTT. These results were interpreted such that the reaction of superoxide with Cya, GSH, NAC, and DTT proceeds to generate sulfinyl radicals and HO $^-$ (reactions 17 and 18) via an intermediary thiol/superoxide complex:

Theoretical calculations confirmed the possibility for a three-electron-bonded superoxide-thiol complex and the likelihood for decomposition into sulfinyl radical and hydroxide.^{66,67} However, the hydrogen peroxide formation observed for the

reaction of superoxide with Cys and Pen suggests that these two thiols may additionally react via hydrogen/electron transfer, directly leading to hydrogen peroxide and thiyl radicals (reaction 19). This reaction could require a proton transfer before electron transfer, that is, conversion of the couple $\text{RSH}/\text{O}_2^{\cdot-}$ to $\text{RS}^-/\text{HO}_2^{\cdot}$ before electron transfer. Interestingly, Jones *et al.*^{68,69} detected $\text{GS}^{\cdot}$ through spin trapping when GSH was exposed to superoxide, suggesting that either a small fraction of the reaction of superoxide with GSH proceeds via reaction (19) or that thiyl radicals are generated subsequently, possibly through the reaction of sulfinyl radicals with GSH (reaction 20). The reported rate constants for the reaction of superoxide with thiols vary between 10^2 and $10^5 \text{ M}^{-1} \text{ s}^{-1}$,⁶⁸ but it appears that values between 10^2 and $10^3 \text{ M}^{-1} \text{ s}^{-1}$ appear most reasonable. On the basis of these relatively low rate constants, thiols will not be able to compete with SOD for superoxide unless specific local conditions allow for a high effective thiol/thiolate concentration in the vicinity of superoxide generation, and/or thiols are part of a transition metal complex (e.g., iron–sulfur clusters).

2.1.4 The Reaction of Cys with NO and NO₂

The S-nitrosation of Cys is key to the regulation of various proteins and biologic pathways.⁴ Nonradical mechanisms of S-nitrosation involve the reaction of thiolate with N_2O_3 , the reaction product of two radicals, NO and nitrogen dioxide (NO_2), as well as *trans*-nitrosation. In addition, a free radical mechanism of S-nitrosation has been suggested, involving the reaction of a thiyl radical with NO (reaction 21)⁷⁰; an alternative mechanism suggested the reaction of NO with thiol in the presence of an electron acceptor.⁷¹ Recently, rate constants of $k_{21} = (2\text{--}3) \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ have been reported for the reaction of thiyl radicals from Cys, GSH, and PenSH with NO,⁷² indicating an efficient radical–radical reaction, which is in contrast to earlier studies suggesting that the reaction of $\text{GS}^{\cdot}$ with NO proceeds with $k < 2.8 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$.⁷³ Of biologic relevance is the question whether thiols react directly with NO,⁷⁴ especially under physiologic conditions of submicromolar concentrations of NO, and $[\text{NO}] \ll [\text{RSH}]$. This question was addressed by Folkes and Wardman,⁷⁵ showing that the anaerobic

reaction of NO with GSH most likely proceeds via reactions (22)–(24):

A kinetic simulation based on reactions (22)–(24) satisfactorily fits not only their results obtained under conditions of $[\text{NO}] \ll [\text{RSH}]$ but also the data of others, obtained under reverse conditions where $[\text{RSH}] \ll [\text{NO}]$. However, the authors conclude that the reaction of NO specifically with GSH is too slow to be of physiological significance. In contrast, the reaction of Cys and GSH with NO_2 proceeds with rate constants of the order of 2×10^7 and $5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, respectively, at pH 7.4 (reaction 25).⁷⁶

2.1.5 The Reaction of Cys with Tyrosyl Radicals

The reaction of tyrosyl radicals with Cys (equilibrium 26) represents an important step in the mechanism of ribonucleotide reductase class I²³:

In addition, pulse radiolysis studies have revealed the importance of equilibrium (26) in several electron-transfer cascades.⁷⁷ More recently, the nitration of Tyr by peroxynitrite has been investigated, where especially in the presence of CO_2 , peroxynitrite decomposes into NO_2 and $\text{CO}_3^{\cdot-}$.⁶⁴ These radicals act in concert, where the reaction of $\text{CO}_3^{\cdot-}$ with Tyr generates the tyrosyl radical, which subsequently recombines with NO_2 . Importantly, no Tyr nitration was observed for model peptides which simultaneously contained both Tyr and Cys, rationalized by the fact that initially generated tyrosyl radicals would be reduced by Cys before recombination with NO_2 .⁷⁸ The rate constant

for the forward reaction of equilibrium (27) was recently determined as $k_{27} = 2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ (pH 7.15).⁷⁹

2.1.6 The Reaction of Cys Thiyl Radicals with O₂

In aerobic environment, thiyl radicals can convert into oxy acids, RSO_nH ($n = 1-3$), via multiple pathways. Thiyl radicals react reversibly with molecular oxygen (equilibrium 28), where $k_{28} = (2.0-2.2) \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ and $k_{-28} = 6.2 \times 10^5 \text{ s}^{-1}$.^{80,81} The electronic structure of the thiyl peroxy radical can be partially described by a charge-transfer state, $\text{RS}^+\text{OO}^{\cdot-}$,⁸² and this species is characterized through a weak absorbance with $\lambda_{\text{max}} = 540 \text{ nm}$.⁸⁰ The chemistry of thiyl peroxy radicals in aerobic solution is complex, and various radical intermediates and products have been characterized for thiyl radicals from GSH, cysteine, penicillamine, and cysteamine through ESR studies in frozen matrices, while kinetic information mostly originates from pulse radiolysis of “simpler” organic thiols, for example, 2-mercaptoethanol. The unimolecular rearrangement (reaction 29) to sulfonyl radicals, $\text{RSO}_2^{\cdot}$, proceeds with $k_{29} \approx 10^3 \text{ s}^{-1}$ ⁸¹ and is associated with a high energy of activation (circa 45 kcal mol^{-1})⁸³:

The sulfonyl radical can further react with oxygen, to yield sulfonyl peroxy radicals (equilibrium 30), where, measured representatively for methyl sulfonyl radicals, $k_{30} = 1.1 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ and $k_{-30} < 10^5 \text{ s}^{-1}$.⁸⁴:

Excess thiols serve as hydrogen donors to thiyl peroxy radicals, sulfonyl radicals, and sulfonyl peroxy radicals, yielding sulfenic acid, sulfinate acid, and sulfonate (reactions 31–34).^{85,86}:

Reaction (33) leads to peroxysulfonic acid, which may be reduced through excess thiol to sulfonic acid (reaction 34):

Sulfinate and sulfonate have been observed as stable oxidation products of Cys in peptides and proteins. In contrast, sulfenic acid is unstable and rapidly reacts with excess thiol to form disulfide unless such a reaction is prevented through the location of the sulfenic acid in a protein domain that does not permit access of thiol.⁸⁷

2.2 Selenocysteine

The low BDE of the Se–H bond (310 kJ mol^{-1}),¹⁴ the low standard reduction potential $E^0(\text{RSe}^{\cdot} + \text{e}^- + \text{H}^+) = +0.77 \text{ V}$ (compare with $E^0(\text{RS}^{\cdot} + \text{e}^- + \text{H}^+) = +1.33 \text{ V}$), and the selenol $\text{pK}_a \approx 5.2$ render selenocysteine (CysSeH) a powerful antioxidant, which has been observed to catalyze the reduction of benzyl viologen by DTT.¹⁴ As for thiols, hydrogen or electron transfer from selenocysteine generates selenyl radicals, $\text{CysSe}^{\cdot}$:

On the basis of the thermodynamic properties listed above, selenyl radicals are expected to be significantly weaker oxidants compared to thiyl radicals. However, $\text{CysSe}^{\cdot}$ radical chemistry has not been explored to the same extent as has been for $\text{CysS}^{\cdot}$ radicals. Critical to the time-resolved detection of $\text{CysSe}^{\cdot}$ are its UV properties, where some open questions remain to be addressed. When Kolano *et al.*⁸⁸ photolyzed (266 nm) dimethyl bis(*N*-*tert*-butoxycarbonyl)-L-selenocysteine in acetonitrile, they observed two transients absorbing with $\lambda_{\text{max}} = 335$ and 450 nm . In contrast, no 450-nm absorbance was detected on photolysis of [(fluorenylideneamino)oxycarbonyl]methyl(*N*-*tert*-butoxycarbonyl)-L-selenocysteine. Tamba and Badiello⁸⁹ used pulse radiolysis to generate $\text{CysSe}^{\cdot}$ via one-electron reduction of low concentrations of selenocystine, and observed a 460-nm absorbance,

assigned to CysSe[•], an observation also made by Nauser *et al.*¹⁴ when they oxidized CysSeH with azide radicals (N₃[•]) in acidic solution. Both groups also described the spectral properties of a diselenide radical anion, for which they reported an absorption with $\lambda_{\text{max}} = 440$ and 455 nm, respectively. Especially the latter value is very close to the reported absorption for CysSe[•] so that both species may not be easily distinguishable. Complicating matters, Mishra *et al.*^{90,91} oxidized various concentrations of selenocystine with HO[•] radicals and other one-electron oxidants and observed that especially at high concentrations of selenocystine and pH > 4, an initial selenocystine radical cation, [CysSeSeCys]⁺⁺ (absorbing with $\lambda_{\text{max}} = 560$ nm), converted into a species absorbing with $\lambda_{\text{max}} = 460$ nm, assigned to a complex of CysSe[•] with nonoxidized selenocystine. Analogous complexes had been observed for thiyl radicals in the presence of high concentrations of disulfides.⁹² Hence, to date, the formation of CysSe[•] has been associated with at least three transient species absorbing around 460 nm, CysSe[•] itself, its diselenide radical anion complex with CysSe[•], and a complex of CysSe[•] with selenocystine. This manifold of transients will require careful experimental optimization when reactions of CysSe[•] need to be studied.

2.3 Protein Cysteine

The reactions outlined above for Cys, GSH, and CysSeH will proceed to various extents for protein Cys and CysSeH, where radical and product yields will depend largely on the respective pK_a values (note that Cys pK_a values can vary between 5.0 and ca. 10.75),^{33,35} conformational properties, and the accessibility to reactant sites. For example, a Cys thiyl radical generated in the vicinity of a second, nonoxidized thiol/thiolate will efficiently form disulfide radical anions in an *intramolecular* reaction. The reaction of the disulfide radical anion with oxygen will then yield disulfide and superoxide, that is, the initial formation of a thiyl radical in the presence of oxygen will lead to the two-electron oxidation product (disulfide). Protein Cys thiyl radicals will also have the opportunity to abstract hydrogen atoms from suitably located amino acids within the three-dimensional structure, and evidence for such hydrogen transfer reactions was provided for human insulin.⁷

For proteins containing both Cys and CysSeH in an appropriate conformation, such as mammalian thioredoxin reductase (TRR), there is the possibility for the formation of selenium–sulfur bonds, R–Se–S–R, and selenium–sulfur bond radical anions, [R–Se–S–R]^{•–}. On the basis of model studies on the one-electron reduction of DTT, diselenothreitol, and selenothiolthreitol, Nauser *et al.*⁹³ have forwarded the hypothesis that the single CysSeH residue in TRR, located in the sequence Gly–Cys–CysSeH–Gly, may protect TRR from deleterious reactions of a thiyl radical by providing a one-electron redox equivalent such that a thiyl radical, Gly–CysS[•]–CysSeH–Gly, would react via *intramolecular* electron transfer with the deprotonated CysSeH residue ($pK_a = 5.2$) to yield a selenyl radical, Gly–Cys–CysSe[•]–Gly. Because of the low Se–H BDE (310 kJ mol^{–1}), the selenyl radicals are not expected to react with protein C–H bonds such as described for thiyl radicals.

3 THIOETHERS AND SELENOTHIOETHERS

Free radicals can react with thio- and selenoethers via homolytic substitution^{94,95} (see **Intramolecular Homolytic Substitutions in Synthesis**) or electron transfer.^{90,96,97} Electron-transfer reactions have been studied in quite detail for the thioether- and selenoether-containing amino acids methionine (Met) and selenomethionine (SeMet), and these have been reviewed in detail below. More recent reports also focused on the reaction of Met with hydrogen atoms (H[•]).

3.1 Methionine

3.1.1 Reaction of Methionine with Oxidizing Radicals

Reaction of Met with the Hydroxyl Radical

The reaction of Met with hydroxyl radicals (HO[•]) was characterized in great detail through radiation chemical methods such as pulse radiolysis and γ -radiolysis.⁹⁸ This reaction proceeds via addition of HO[•] to the sulfur (reaction 36), resulting in a hydroxysulfuranyl radical. Subsequent reactions of this hydroxysulfuranyl radical depend on various parameters such as the nature of the

Met-containing substrate (i.e., whether the reaction involves the free amino acid Met, peptide-bound Met, or protein-bound Met), the concentration of the Met-containing substrate, and pH:

three-electron-bonded intermediate was also obtained for the reaction of HO $\cdot$ with peptides containing an N-terminal Met residue.⁹⁹ An important feature of water elimination from the

Hydroxysulfuranyl radicals of free Met decompose via three competitive pathways: protonation followed by the elimination of water, where the proton is either derived from the solvent (pH < 3; reaction 37) or the N-terminal amino group (pH > 3; reactions 38 and 39), and reaction with a second Met (reaction 40). Reactions (38) and (39) lead to a very short-lived sulfur–nitrogen three-electron-bonded intermediate ($> \text{S} \cdot \text{NH}_2\text{R}^+$), which formally exists in equilibrium with a Met sulfur radical cation. Ultimately, this reaction sequence results in the formation of CO $_2$ and an α -amino-substituted carbon-centered radical (reaction 43). The latter reacts in a diffusion-controlled manner with molecular oxygen, ultimately forming superoxide and 3-(methylthio)propanal (methional) (reactions 44 and 45).¹¹ Evidence for a sulfur–nitrogen

hydroxysulfuranyl radical at pH > 3 is the ability of the protonated N-terminal amino group to function as a proton donor. The question arises whether such proton transfer is also possible over longer distances, that is, when Met is incorporated into peptides. Experiments with γ -Glu-Met and γ -Glu-Gly-Met-Gly revealed a circa 50% efficiency for decarboxylation according to reactions (46)–(49) for both peptides at pH 5.9–6.4,¹⁰⁰ suggesting that proton transfer, followed by formation of a sulfur–nitrogen three-electron-bonded intermediate, can occur when Met is not the N-terminal amino acid:

Pulse radiolysis experiments on the nanosecond timescale revealed formation of a sulfur–nitrogen three-electron-bonded intermediate also for *S*-methylglutathione.¹⁰¹ Additional support for

the interaction of Met hydroxysulfuranyl radicals with the N-terminus is derived from experiments with Thr-(X)_n-Met,^{102,103} where a fraction of the sulfur–nitrogen three-electron-bonded intermediate suffers $C_\alpha-C_\beta$ cleavage of the Thr residue, generating acetaldehyde (CH_3CHO) (reactions 50–53). No significant difference in the efficiency of acetaldehyde formation was observed between Thr-Met and Thr-Gly-Met, while only a circa 30% reduction was observed when comparing Thr-Met with Thr-(Gly)₄-Met.¹⁰³ Hence, a flexible Gly-containing sequence permits the interaction of Met hydroxysulfuranyl radicals with the N-terminus. In contrast, incorporation of a single Pro residue between Thr and Met (i.e., in Thr-Pro-Met) results in a significant reduction (by >70%) in the efficiency of acetaldehyde formation, suggesting that the Pro residue provides a barrier for *intramolecular* proton transfer and formation of the sulfur–nitrogen three-electron-bonded intermediate:

It remains to be shown to what extent proton transfer reactions between Met hydroxysulfuranyl radicals and proton donors (His, Lys, and Arg) may promote sulfide radical cation formation in proteins. In this respect, we note that $HO^\bullet$ radicals

can not only originate from the exposure of aqueous solutions to ionizing radiation, but that $HO^\bullet$ (and/or their metal-bound equivalents) will be generated by Fenton reactions. In fact, acetaldehyde was observed on exposure of Thr-Met to a Fenton system consisting of $[Fe(II)(EDTA)]^{2-}$ and H_2O_2 , though control experiments with a Met-deficient peptide, Thr-Leu, suggest that under these experimental conditions, a fraction of acetaldehyde could result from a direct oxidation of the N-terminal amino group.¹⁰⁴

Theoretical calculations predict that the sulfur–nitrogen three-electron-bonded intermediate with the N-terminal amino group represents the most stable structure of a one-electron oxidized Met in aqueous solution.¹⁰⁵ This is also reflected in a calculated lower one-electron reduction potential for sulfide oxidation of an N-terminal Met residue as compared to a non-N-terminal Met residue within a peptide.¹⁰⁵ These calculations are *not* a contradiction to the experimental observations presented above, where an interaction between a non-N-terminal Met residue and the N-terminal amino group (e.g., in γ -Glu-Gly-Met-Gly and Thr-Gly-Met) was proposed based on a reaction product (i.e., formation of CO_2 and acetaldehyde). The formation of these reaction products indicates

that the interaction between a Met residue and the N-terminal amino group is kinetically possible but does not allow to quantify an equilibrium constant for the formation of the sulfur–nitrogen three-electron-bonded intermediate.

Interestingly, theoretical calculations predict that sulfur radical cations are not significantly stabilized by interaction with either the oxygen or the nitrogen of an amide bond.¹⁰⁵ These calculations are in contrast to experimental data with a series of *N*-acetyl (*N*-Ac)-substituted peptides (which do not contain a free N-terminal amino group) and with specific organic model compounds of Met, in which Met is embedded into a norbornane frame.

Pulse radiolysis experiments with *N*-Ac-methionyl amide, *N*-Ac-(Gly)₃Met(Gly)₃,¹⁰⁶ and cyclo-Met-Met¹⁰⁷ provided evidence for the formation of both sulfur–nitrogen and sulfur–oxygen three-electron-bonded intermediates with the peptide bond (such as that shown in the following reactions:

In addition, sulfur–oxygen three-electron-bonded intermediates were identified for the reaction of HO[•] radicals with (1*R*,2*S*,4*R*,6*R*)-6-(methylthio)bicyclo[2.2.1]heptane-2-carboxamide (**8-endo**) but not (1*R*,2*R*,4*R*,6*R*)-6-(methylthio)bicyclo[2.2.1]heptane-2-carboxamide (**8-exo**) (Figure 3).¹⁰⁸

Moreover, when HO[•] radicals were reacted with the diketopiperazine-substituted Met analog (1*R*,2*R*,4*S*,6*R*)-6'-methylene-6-(methylthio)spiro[bicyclo[2.2.1]heptane-2,2'-piperazin]-3'-one hydrate (**9**) (Figure 3), time-resolved UV

Figure 3 Structures containing Met embedded into a norbornane frame.

spectroscopy indicated the formation of a sulfur–oxygen three-electron-bonded intermediate, though the width of the UV peak with λ_{max} around 400 nm was significantly smaller compared to analogous UV peaks observed for the Met-containing peptides and **8-endo**.¹⁰⁸ Parallel electrochemical experiments in acetonitrile revealed a significantly lower peak potential for the oxidation of **8-endo** (1.07 V vs Ag/AgNO₃) compared to **8-exo** (1.40 V vs Ag/AgNO₃), consistent with the potential for stabilization of intermediary sulfur radical cations by interaction with the amide bond.

In general, sulfur radical cations decompose by deprotonation, forming α -(alkylthio)alkyl radicals.⁹⁸ However, especially for sulfur radical cations from cyclo-Met-Met, kinetic data revealed additional pathways, based on an incomplete conversion into α -(alkylthio)alkyl radicals.¹⁰⁷ While a detailed characterization of these additional pathways must await further experimental results, our hypothesis for the decomposition of sulfur radical cations of cyclo-Met-Met is summarized in reactions (58)–(60).

The reaction of HO[•] with the protein calmodulin (CaM) in the presence of Ca²⁺, investigated by pulse radiolysis, leads to the formation of an intermediate with λ_{max} circa 390 nm at circa 0.6–1.1 μ s after the pulse.¹⁰⁹ The spectral features of this intermediate display a higher resemblance to a sulfur–nitrogen three-electron-bonded intermediate as

of sulfur–nitrogen three-electron-bonded intermediates would suggest that it does not decompose via *intramolecular* proton transfer such as observed during the reaction of Met with HO[•].⁹⁸ Overall, the reaction of Met with CCl₃OO[•] proceeds with $k = 2.9 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, while the reaction of Met with the less oxidizing peroxy radical CF₃CH(Cl)OO[•] proceeds with $k = 1.4 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$.¹¹¹ For the reaction of less oxidizing peroxy radicals with organic sulfides, an alternative reaction mechanism exists, in which formally an oxygen atom is transferred to the sulfide to yield sulfoxide. However, isotopic labeling experiments in aqueous solution (H₂¹⁶O) saturated with ¹⁸O₂ indicate that the oxygen atom in the sulfoxide originates from water, leading to the mechanism proposed in reaction (63).¹¹²:

$$\begin{aligned} \text{R}^{18}\text{O}^{18}\text{O}-\cdot\text{S}< + {}^{16}\text{OH}_2 \longrightarrow \text{R}^{18}\text{O}\cdot \\ + \text{H}_2{}^{18}\text{O} + >\text{S} = {}^{16}\text{O} \quad (63) \end{aligned}$$

Of potential biological relevance is also the reaction of Met with the carbonate radical ($\cdot\text{CO}_3^-$). As indicated above, this radical is generated through the reaction of peroxynitrite with CO_2 , followed by homolytic dissociation into $\cdot\text{NO}_2$ and $\cdot\text{CO}_3^-$.⁶⁴ While $\cdot\text{NO}_2$ does not react measurably with Met, a rate constant of $3.6 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ has been derived for the reaction of $\cdot\text{CO}_3^-$ with Met.⁶⁴ On the basis of $E^0 = 1.84 \pm 0.1 \text{ V}$ for the reaction $\cdot\text{CO}_3^- + \text{e}^- + \text{H}^+ = \text{HCO}_3^-$,¹¹⁴ it can be assumed that

If such adduct would also form during the reaction of $\text{CCl}_3\text{OO}^\bullet$ with Met, the experimentally observed pH dependence for the formation

$\cdot\text{CO}_3^-$ reacts with Met via one-electron oxidation. However, previous time-resolved experiments have not reported the formation of a sulfur–nitrogen or sulfur–sulfur three-electron-bonded species such as observed for the reaction of Met with $\text{HO}\cdot$.¹¹⁵

3.1.2 Reaction of Met with H'-Atoms

The reaction of Met with H'-atoms is of potential relevance for radiation biology. This reaction involves bimolecular homolytic substitution ($\text{S}_\text{H}2$), via an initial addition of the H'-atom to the sulfur, followed by homolytic carbon–sulfur bond cleavage, and hydrogen transfer from the intermediary CH_3SH , ultimately generating α -aminobutyric acid and methylthiyl radicals ($\text{CH}_3\text{S}\cdot$) (reactions 64–66).¹¹ These processes have been documented for both free and peptide- and protein-bound Met.^{11,116,117}

3.2 Selenomethionine

The reactions of $\text{HO}\cdot$ radicals with selenomethionine proceed analogous to the reactions with Met, except that a selenium–nitrogen three-electron-bonded intermediate, formed via water elimination from an initial $\text{HO}\cdot\text{-Se}$ adduct, is significantly more stable.^{118,119}

4 CONCLUSION

The reactions of free radicals with S- and Se-containing amino acids are reviewed. These

reactions encompass hydrogen and electron transfer as well as homolytic substitution. Future experimental work shall focus in particular on radical transfer reactions in proteins, where sites of ultimate damage may evolve quite remote from sites of initial free radical attack. These mechanisms may rationalize some of the biological effects of free radicals.

Oxidative Damage to Proteins

Michael J. Davies

The Heart Research Institute, University of Sydney, Sydney, New South Wales, Australia

1 INTRODUCTION

Biological systems are continually exposed to both endogenous and exogenous sources of oxidants (Table 1). Under normal circumstances, the formation and subsequent reactions of such oxidants are kept in check by a battery of defensive systems within cells and organisms. These defenses include low molecular mass scavengers (e.g., ascorbic acid, tocopherols, urate, and thiols), enzymes that remove either oxidant precursors or the oxidants themselves (e.g., superoxide dismutases (SODs), catalases, peroxiredoxins, and glutathione peroxidases), and enzyme systems that can repair (methionine sulfoxide reductases (Msrs), disulfide reductases/isomerases, and sulfiredoxins) or remove (proteasomes, lysosomes, and DNA repair enzymes) damaged materials.

Despite the range and diversity of these protective systems, it is now clear that enhanced oxidative damage can occur in a wide range of human, animal, and plant pathologies. This may arise as a result of either increased oxidant formation, a failure or decrease in activity of the defense systems, or both of these simultaneously. In some diseases, it is clear as to which factor is primarily responsible for the imbalance (e.g., exposure to high energy radiation, genetic faults that result in decreased levels, or absence of repair enzymes), but in many cases, it would appear that both factors play a role, as many of the defensive systems are themselves subject to oxidation or have a requirement for cofactors that can be readily depleted/oxidized.

The processes outlined in Table 1 can result in the formation of a wide range of different oxidants (both radical and two-electron) being generated *in vivo* (Table 2). These species vary markedly in their reactivity and the damage that they induce is highly variable and complex. Some of these species are highly reactive, such as HO[•], and oxidize nearly all biological targets, with rate constants near the diffusion limit (Table 3). As a result of the abundance of such targets *in vivo*, it is likely that this radical will only cause damage within a very short distance from its locus of formation—that is, the damage induced by this species is site specific to its place of formation.

Many of the oxidants listed in Table 2 are much less reactive than HO[•], and their corresponding rates of reaction with biological materials will be somewhat slower and target/environment dependent. Some of these species can therefore diffuse through considerable distances from their sites of formation and cause damage at a distance. Furthermore, it is well established that many of these species can interconvert and give rise to secondary oxidant species, which may have very different reactivities and lifetimes than the initial species (Figure 1).

A number of groups have calculated approximate diffusion distances for biological oxidants (e.g., Ref. 2) with these values ranging from <0.2 μm for HO[•] to 1.5 mm for H₂O₂ (cf. a typical cell diameter of 20 μm). The reactivity of particular oxidants with a specific target material can vary by >10 orders of magnitude and hence the lifetime

Table 1 Examples of endogenous and exogenous factors that result in oxidant formation.

Endogenous	Exogenous
Electron transport chains (mitochondria, endoplasmic reticulum, plasma membrane)	Radiation (high energy, UV, visible light + sensitizer, thermal)
Heme protein/enzyme reactions	Sulfur oxides
Peroxidases	Nitrogen oxides
Nitric oxide synthases	Particulates (e.g., diesel particles)
NADPH oxidases	Mineral fibers and dusts (e.g., asbestos)
Xanthine oxidase	Ozone
Lipoxygenases	Metabolism of chlorinated hydrocarbons, drugs, nitro compounds, paracetamol, ethanol
Prostaglandin synthases	Oxidized foodstuffs
Auto-oxidation of glucose, thiols, catecholamines, metal ions	

NADPH, nicotinamide adenine dinucleotide phosphate.

of biological oxidants can be enormously different (submicroseconds to many days). Table 4 provides rate constants for the reaction of a number of oxidants with the amino acid methionine (Met) to illustrate this diversity. It should be noted, however, that these data must be treated with care, as the reactivity of some targets is critically dependent on the environment; this is amply illustrated by Table 5, which provides rate constant data for reaction of the amino acid cysteine (Cys) with a number of oxidants. In this particular case, there is also a vast difference in the rate constants with this encompassing ~seven orders of magnitude; however, with this amino acid, the rate constants for reaction with the *same* oxidant vary over the same range simply as a result of environmental factors that make some Cys residues (e.g., those in peroxiredoxin proteins^{3,4}) much more rapid than the same species in other proteins (e.g., bovine serum albumin⁵).

2 PROTEINS AS MAJOR TARGETS FOR OXIDATION

It is well established that the extent of damage to particular targets depends on a number of factors including

Table 2 Selected reactive oxidants postulated to be formed *in vivo*.

Hydroxyl (HO [•])	Nitric oxide (NO [•])
Superoxide radical anion (O ₂ ^{•-})	Peroxynitrite (ONOOH)
Hydroperoxyl (HOO [•])	Peroxynitrosocarbonate (ONOOCO ₂ ⁻)
Peroxyl (ROO [•])	Nitrogen oxides (NO ₂ [•] /NO ₃ [•])
Alkoxyl (RO [•])	Nitrogen-centered radicals (RNH [•])
Hydrogen peroxide (H ₂ O ₂)	Thiyl radicals (RS [•])
Alkyl/aryl hydroperoxides (ROOH)	Perthiyl radicals (RSS [•])
Dialkyl/aryl/endoperoxides (ROOR)	Disulfide radical anions (RSSR ^{•-})
Singlet oxygen (¹ O ₂)	Sulfur trioxide radical anion (SO ₃ ^{•-})
Ozone (O ₃)	Alkyl/aryl radicals (R [•])
Hypochlorous acid (HOCl)	Excited state species
Hypobromous acid (HOBr)	α-Dicarbonyls
Hypothiocyanous acid (HOSCN)	α-Hydroxycarbonyls
Phenoxy radicals (aromatic-O [•])	α-Aminocarbonyls
Semiquinone radicals	α, β-Unsaturated aldehydes
Quinones	Carbonate radical anion (CO ₃ ^{•-})
Quinimines	

Table 3 Selected rate constants for reaction of HO[•] with biological macromolecules and antioxidants.^a

Target	Rate constant (M ⁻¹ s ⁻¹)
DNA	8 × 10 ⁸
RNA	1 × 10 ⁹
Hyaluronan	7 × 10 ⁸
Linoleic acid	9 × 10 ⁹
Collagen	4 × 10 ¹¹
Albumin	8 × 10 ¹⁰
Ascorbate	1 × 10 ¹⁰
GSH	1.4 × 10 ¹⁰
Trolox C (water-soluble analog of α-tocopherol)	6.9 × 10 ⁹

^aData from Ref. 1.

1. the concentration of target
2. the rate constant for reaction of oxidant with target
3. the location of target versus oxidant
4. the occurrence of secondary damaging events
5. the occurrence of transfer reactions and
6. the possibility of repair and scavenging reactions.

Figure 1 Interconversion of some biological oxidants. [Adapted from Ref. 2. © Nature Publishing Group, 2008.]

Table 4 Selected rate constants for reaction of some biological oxidants with the amino acid methionine.^a

Reactant	Rate constant (M ⁻¹ s ⁻¹)
HO•	7 × 10 ⁹
CO ₃ • ⁻	1.2 × 10 ⁸
HOCl	3.8 × 10 ⁷
Singlet oxygen	2 × 10 ⁷
Ozone	5 × 10 ⁶
CF ₃ CHClOO•	1.4 × 10 ⁶
N ₃ •	<10 ⁶
ONOO ⁻ /ONOOH	3.6 × 10 ²
O ₂ • ⁻	<0.3
H ₂ O ₂	2 × 10 ⁻²
NO•	Very slow

^aData from Refs 1 and 6.

Clearly, a number of these factors cannot be readily generalized; however, there is considerable evidence that (1) and (2) can be the major driving forces. In this respect, it is worth noting that proteins comprise the major (nonwater) components of most biological systems. Thus, in plasma, proteins are present at ~70 g protein dm⁻³, with all other components being present at <5 g dm⁻³; in liver tissue, proteins account for ~140 g kg⁻¹ wet mass, with lipid ~50 g kg⁻¹, and all other components <10 g kg⁻¹; and for leukocytes, proteins are present at ~100 g per 10¹² cells with all other components present at <20 g per 10¹² cells.⁶ This predominance of proteins over all other components bar water provides a strong indication that proteins

Table 5 Selected rate constants for reaction of some biological oxidants with the amino acid cysteine.^a

Reactant	Rate constant (M ⁻¹ s ⁻¹)

^aData from Refs 3–5 and 7–9.

are major targets for oxidants in most biological systems. Using such abundance data and published compilations of rate constants, it is possible to carry out very approximate “back-of-the-envelope” calculations as to the fate of particular oxidants in cells. Using such an approach, it has been concluded that for leukocyte cells, ~69% of HO• generated within these cells, by, for example, γ -radiation (a relatively “clean” source of this species), will be consumed in reactions with proteins,¹⁰ and the corresponding data for singlet oxygen (¹O₂) is ~68%.¹¹ Such figures need, however, to be treated with extreme caution as they employ an extrapolation from homogenous reaction kinetics to highly complex, compartmentalized systems. It should also be noted that *major* does not always equate to the *most important* with regard to etiology of a disease.

In the subsequent sections of this review, the chemistry and mechanisms of damage to proteins induced by some of the oxidants listed in Table 2 are discussed. The various processes that give rise to these radicals and other oxidants will not be covered further here in any detail, as they have been covered extensively in other articles and books (e.g., Ref. 12).

3 REACTION OF RADICALS WITH PROTEINS

Radicals undergo a variety of reactions, including hydrogen abstraction, electron transfer (oxidation or reduction of the substrate), addition, fragmentation and rearrangement, dimerization, disproportionation, and substitution (concerted addition and elimination) reactions with amino acids, peptides, and proteins. These reactions have been the subject of a number of previous reviews (e.g., Refs 6, 11, 13–30). This article therefore concentrates on the reactions of radicals with proteins (and some peptides) rather than free amino acids and is a broad overview of the major processes that occur, rather than an exhaustive catalogue.

A multitude of different radicals can be generated on proteins by biologically relevant radicals. This arises from reaction with both the protein backbone and the 20 common amino acid side chains, most of which have multiple possible sites of attack. The nature of the radicals formed on proteins depends critically on the nature and reactivity of the attacking radical.

Electrophilic radicals are more commonly encountered *in vivo*, and such radicals, including oxygen-derived radicals such as alkoxyl and peroxy species, preferentially oxidize electron-rich sites. Nucleophilic species (such as phenyl and some other carbon-centered radicals) preferentially attack electron-deficient sites, but these species are relatively rare *in vivo* due to the rapid reaction of these species, once formed, with molecular oxygen with subsequent formation of peroxy radicals. With free amino acids, the positional selectivity of radical attack is well understood. There is some variation in the magnitude of the rate constants for reaction of species such as HO $\cdot$, with the rate constants ranging from $1 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ for Gly to circa $1 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ for Trp, His, and Cys.¹ This arises from preferential attack at sites remote from the powerfully electron withdrawing amine group

on the α -carbon of free amino acids. Thus, with free amino acids, attack at side-chain sites predominates. This effect of the amine group is exerted over long distances with attack on large side chains (e.g., Val, Leu, and Ile) skewed toward remote positions.^{31–34} The ratio of attack at potential sites is also partly dictated by the greater stability of the resulting tertiary > secondary > primary carbon-centered radicals.^{34–38} The selectivity of side-chain attack is also affected by functional group that can stabilize or destabilize the resulting radicals. Thus, hydrogen atom abstraction occurs preferentially adjacent to hydroxyl groups (in Ser and Thr), carboxyl and amide functions (in Asp, Glu, Asn, and Gln), and the guanidine group of Arg.^{39–50} The protonated amine of the Lys side chain results in hydrogen abstraction at sites remote from both the side chain and backbone amine groups with abstraction predominantly from C4 and C5.^{35,36,41,51}

Addition reactions are typically faster than atom abstraction reactions, due to the more favorable transition state energies, and hence addition to Phe, Tyr, Trp, and His and the sulfur atoms of Met and cystine predominate over abstraction reactions from the $-\text{CH}_2$ groups present in these species.^{52,53} In contrast, hydrogen abstraction from the thiol ($-\text{SH}$) group of Cys is very fast, resulting in thiyl radical ($\text{RS}\cdot$) formation.^{15,54–56}

In proteins, this selectivity is less marked because of the conversion of the protonated amine on the α -carbon into a peptide (amide) bond. This results in a greater rate constant, and hence extent, of reaction by hydrogen atom abstraction from α -carbon site.¹ This results in enhanced backbone oxidation and subsequent fragmentation.^{33,57} The removal of the deactivating influence of the amine function results in faster reaction at all sites, with the range of the rate constants for HO $\cdot$ attack on N-acetylated amino acids being much smaller ($2\text{--}7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$) than for the free zwitterion species.²⁴ For larger peptides, the rate constants for HO $\cdot$ reaction are all $\sim 10^9\text{--}10^{10} \text{ M}^{-1} \text{ s}^{-1}$,¹ irrespective of the side chains present.

The α -carbon radical formed by hydrogen atom abstraction from the backbone is stabilized by electron delocalization on to both the amide and the carbonyl functions on the N- and C-terminal sides, respectively,^{58,59} although the extent of this effect is dependent on the nature of the side chains (due to steric and electronic interactions arising from the need for planarity) and the local

protein structure (helix, sheet, etc.). These effects result in a greater stability of the α -carbon radical formed on Gly residues compared to the tertiary α -carbon radical formed, for example, from Ala or Val residues,^{19,60,61} due to the steric constraints required to achieving planarity at the α -carbon.^{62,63} This results in significant backbone damage as well as at side-chain oxidation, although an exact quantification of this effect has not been achieved.

With larger materials, secondary and tertiary structures appear to be a major influence. Theoretical calculations indicate that α -carbon radical stability varies with secondary structure as a result of the constraints that such structure plays on radical geometries, with a preference for α -carbon radical formation at Gly residues in anti-parallel β -sheets.^{64–66} Secondary and tertiary structures may also influence the access of radicals present in bulk solution to backbone sites as a result of the protrusion of the side chains. This may indicate that side-chain reactions are of greater importance for globular or sheet proteins, than for disordered structures or random-coil peptides.

Selectivity of damage becomes more marked with less reactive attacking radicals. This can be rationalized by the presence of late transition states with less reactive radicals, in which there is significant radical character at the incipient radical site; as a result, radical stabilizing factors become more important. Thus, selective damage is typically observed on peptides and proteins by the oxidants present below HO $\cdot$ in Table 4 (see also Ref. 19). A summary of the major sites of attack by a wide range of reactive species is given in Table 6.

A confounding factor in examining sites of radical attack on proteins arises from the observation of chain reactions, with a greater concentration of

amino acids modified than initial attacking radicals generated. Chain lengths of up to 15 have been reported (i.e., 15 amino acids modified per HO $\cdot$ generated⁶⁷). Such chain lengths are modest by comparison with lipid peroxidation, where values >100 have been detected, but these are still large enough to confound analyses. The protein-derived chain-carrying species are poorly defined, but oxygen consumption during these reactions is modest (~ 2 moles per mole attacking radical), indicating that nonoxygen-dependent reactions play a major role.⁶⁷

Selective damage to particular residues of proteins can arise from metal ion binding at particular side-chain sites.²² Evidence has been presented for site-specific radical formation on proteins, including catalase,^{68,69} bovine serum albumin (BSA),⁷⁰ and β -amyloid precursor protein⁷¹ among others. In each case, well-defined protein fragments were detected and ascribed to complexation/binding of the metal ion to particular sites and subsequent generation of highly reactive species that would be expected to react in their immediate vicinity thereby inducing site-selective damage. With thyrotropin-releasing hormone, copper complexation has been proposed to occur at the His residue in the sequence $\sim$ Glu–His–Pro $\sim$, with HO $\cdot$ abstracting a hydrogen atom from the α -carbon site of Pro.⁷² Subsequent reaction with O $_2$ gives backbone cleavage, with formation of an aldehyde and a new N-terminal amide ($\sim$ Glu–His–Pro–NH $_2$). Selective modification of His residues has also been reported for glutamine synthetase^{73,74} and human growth hormone.⁷⁵ Specific side-chain modification of Met residues has been reported for peptides treated with Fe $^{3+}$ /O $_2$ /ascorbate,⁷⁶ His, and Met in human relaxin treated with similar mixtures,⁷⁷ and Trp loss in peptides exposed to Fe $^{3+}$ /O $_2$ $^{\cdot-}$.⁷⁸ The enhanced loss of particular amino acids exposed to metal ion generated, compared to radiolytic, HO $\cdot$ has been ascribed to a similar phenomenon, with the enhanced loss of His, Cys, Met, Lys, Arg, and Trp to metal ion binding (reviewed in Ref. 22). In other systems, metal ion-peroxy species, high oxidation state Ni $^{3+}$ complexes, and H $_2$ O $_2$ have been invoked.^{76,78–80} Formation of metal ion–hydroperoxide complexes (M $^{n+}$ –OOH) has been demonstrated in some systems with these used to carry out site-specific cleavage on proteins (e.g., Refs 81–83). Localization of the metal ion at a particular site allows the three-dimensional structure in the vicinity of the

Table 6 Selectivity of damage to protein side chains by reactive oxidants.

Oxidant	Major sites of damage
HO $\cdot$	Most residues
1 O $_2$	Cys, Met, Trp, Tyr, and His

HOSCN	Cys

metal ion to be probed.^{84,85} Site-specific damage has also been defined in sugar-mediated reactions, particularly during metal-ion catalyzed oxidation, or autoxidation, of sugar molecules covalently linked to proteins as a result of glycation reactions.^{86–90}

4 FATE OF PROTEIN RADICALS

4.1 Side-Chain Carbon-Centered Radicals

Reaction of most radicals with proteins results in the initial formation of carbon-centered radicals either via hydrogen abstraction from C–H bonds (side chain or α -carbon) or from addition of an initial radical to an aromatic ring. Carbon-centered radicals can also be generated via secondary reactions of other species, such as rearrangement and fragmentation reactions of alkoxyl,^{15,91–94} peroxy,^{95–99} or nitrogen-centered radicals (reactions 1–3).^{100,101}

In the presence of O_2 , which is ubiquitous in most biological systems, these carbon-centered species usually yield peroxy radicals with rate constants near the diffusion-controlled limit ($k = 10^9\text{--}10^{10} \text{ M}^{-1} \text{ s}^{-1}$). In the absence of O_2 , dimerization or disproportionation is the major fate. The rate constants for the latter processes are structure dependent and this can be a major factor governing protein radical behavior. Furthermore, as dimerization/disproportionation involves two radicals, which are usually present only at very low concentrations, reaction with O_2 typically predominates. One major exception is with highly stabilized/delocalized radicals (e.g., Tyr-derived phenoxyl radicals) where dimerization (k circa $5 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$), through either the oxygen atom or carbon atoms on the aromatic ring, is not markedly affected by O_2 .^{102–104}

Hydrogen atom abstraction by carbon-centered species can also occur with suitable donors containing weak X–H bonds (typically thiols). This can be of significance when the concentration of

O_2 is low, where the radical is stabilized, and/or when dimerization reactions are prevented by steric constraints (e.g., protein structure). This process typically results in “repair” of the carbon-radical and formation of a secondary species (e.g., thiyl radicals; reaction 4).^{55,105} Recent studies have shown that these reactions can be of significance with α -carbon (backbone) radicals, with repair occurring by neighboring Cys residues; a special case of this process is internal repair within Cys residues (i.e., transfer from the Cys α -carbon site to the thiol within the same residue).

Some suitably substituted carbon-centered radicals also undergo (slow) unimolecular elimination reactions. Thus, some α -hydroxyalkyl radicals with β -amino groups release ammonia (reaction 5).¹⁰⁶ This process may be significant with radicals formed at C5 on 5-hydroxylysine.

4.2 Peroxyl Radicals

In addition to formation by O_2 addition to carbon-centered radicals, peroxy radicals can also be generated from metal ion-catalyzed decomposition of hydroperoxides (reaction 6).^{107,108}

These radicals undergo multiple reactions that generate hydroperoxides, alcohols, and aldehydes or ketones. The former of these appear to arise predominantly from either hydrogen atom or electron abstraction reactions, with the latter followed by rapid protonation of the anion (reactions 2 and 7). These processes are the likely source of the high yields (up to ~65% of the initial radical yield) of hydroperoxides detected on exposure of proteins to a wide range of radicals in the presence of O_2 . These species have been detected on most side chains, and particularly those with large numbers of C–H bonds (e.g., Val, Leu, Ile, Glu, Lys, and Pro). While the nature and yield of these species have been explored in some detail with free amino

acids and small peptides,^{109,110} the nature and sites of these species on intact proteins and larger peptides is poorly understood, due to the complexity of these systems and the instability of these materials.

Peroxyl radicals can also undergo dimerization reactions with another peroxyl radical or other species (e.g., $\text{HOO}^\bullet/\text{O}_2^{\bullet-}$; reactions 8–12) that yield carbonyls and alcohols or alkoxy radicals.^{95–99}

Peroxyl radicals with α -substituted heteroatoms (α -hydroxyl or α -amino groups) undergo rapid unimolecular elimination reactions with loss of $\text{HOO}^\bullet/\text{O}_2^{\bullet-}$ (reactions 13–14).^{111–116} Thus, peroxyl radicals formed at C6 on lysine side chains (via carbon-centered radicals) readily eliminate NH_4^+ and $\text{HOO}^\bullet$ to yield α -amino adipate- δ -semialdehyde.¹¹⁷ Similar reactions are likely to occur with peroxyl radicals formed at the β -carbon on Ser and Thr residues, with this underlying the very low yields of hydroperoxides detected on irradiation of these amino acids. These reactions result in the formation of the corresponding aldehyde (from Ser) or ketone (from Thr). Similar reactions have been postulated to be of major importance in backbone fragmentation (see below). This type of elimination reaction is also of significance when peroxyl radicals are generated on aromatic rings after initial radical addition (reaction 15).¹¹⁸ These reactions may be key processes in protein chain oxidation reactions as they result in damage to one amino acid and the release of a further radical species that can propagate damage.

(15)

The factors that determine the yield of these various potential products on peptides and proteins have yet to be fully elucidated with little kinetic data available for the reactions. Factors that are likely to play a major role include (i) the rate of reaction of the initial carbon-centered radical with O_2 (usually $k = 10^9\text{--}10^{10} \text{ M}^{-1} \text{ s}^{-1}$), (ii) the rate of reaction of the peroxyl radical with hydrogen atom or electron donors, (iii) the radical flux and hence the rate of radical–radical reactions, (iv) steric and electronic constraints that will affect the partition between bi- and unimolecular reactions, and (v) the stability of intermediate species, such as hydroperoxides and tetroxides. It is however clear that this multitude of reactions can result in a wide range of different materials, principally hydroperoxides, alcohols, and aldehydes and ketones, and also some fragmented and dimerized species, from aliphatic side chains on proteins. Some of the products arising from these reactions are listed in Table 7.

4.3 Alkoxy Radicals

Alkoxy radicals formed from peroxyl radical reactions (e.g., reaction 9) or one-electron reduction of hydroperoxides undergo rapid addition and hydrogen abstraction reactions and a number of facile unimolecular fragmentation and rearrangement reactions.^{15,91–94} Primary and secondary alkoxy radicals undergo rapid (formally 1,2-) hydrogen shift reactions in aqueous solution (reaction 1; k circa $10^6\text{--}10^7 \text{ s}^{-1}$) to give α -hydroxyalkyl radicals.^{91,92,119} These reactions compete with intramolecular hydrogen abstraction to give alcohols.^{92,119} Tertiary alkoxy radicals, where 1,2-hydrogen shift reactions are impossible, undergo rapid ($k \sim 10^6 \text{ s}^{-1}$) β -fragmentation reactions to give a carbon-centered radical and

an aldehyde/ketone.^{93,120–122} These reactions may result in transfer of damage from a β -carbon side-chain site to the backbone, as a result of the stability of the α -carbon radical, and release of the side chain from the protein as a low molecular mass aldehyde/ketone (reaction 16).^{123,124} β -Scission of an alkoxy radical formed at C4 on Glu side chain has been shown to result in the loss of the adjacent side-chain carboxyl group as CO₂^{•-} (reaction 17).¹⁰⁷

Other side chain-derived alkoxy radicals may also transfer damage to the α -carbon site. Thus, alkoxy radicals at C5 on Lys might be expected to readily abstract an α -carbon hydrogen atom via an intramolecular 1,5-hydrogen atom shift (reaction 18); direct evidence for this process is lacking, although such reactions occur rapidly with model compounds (k circa $8 \times 10^6 \text{ s}^{-1}$) even when the product radical is poorly stabilized. Similar reactions may occur with C5 alkoxy radicals on the side chains of Arg, Ile, and Leu. 1,4-Hydrogen shifts are less favorable, and hence slower, than 1,5 (and 1,6) reactions.

4.4 Nitrogen-Centered Radicals

Nitrogen-centered radicals generated via cleavage of N–Cl bonds (see section on hypohalous acids; reaction 19) can undergo rearrangement reactions analogous to those of alkoxy radicals described above to give carbon-centered radicals.^{100,101} Direct formation of nitrogen-centered radicals by hydrogen atom abstraction from amine groups (e.g., that on free Gly) by HO[•] has also been demonstrated.¹²⁵ The significance of such reactions with amine and amide groups on proteins is yet to be determined.

Intramolecular hydrogen atom abstraction appears to be particularly favored with aminyl radicals (e.g., those potentially formed from the ϵ -amino group of Lys side chains), with this having the potential to generate carbon-centered radicals at other side-chain sites or at the α -carbon.^{100,101} The latter is an example of potential side chain to backbone radical transfer and may be of significance in the induction of protein backbone cleavage by these species; such reactions remain to be explored in depth.

4.5 Radicals Formed on Sulfur-Containing Amino Acids

Thiyl radicals ($RS^\bullet$) can be generated on proteins by direct hydrogen, by cleavage of disulfide linkages (e.g., by UV light or electron attachment), or by repair of other radicals (see above).^{126,127} Thiyl radicals react rapidly, but reversibly, with O_2 to form peroxy radicals $RSOO^\bullet$ (reaction 20), which can isomerize to give sulfonyl radicals $RS(=O)O^\bullet$ and hence oxyacids and sulfinyl ($RSO^\bullet$) radicals.^{27,128} At physiological pHs, reaction with a further thiolate anion (RS^-) to give a disulfide radical anion (reaction 21) can compete with reaction with O_2 .^{15,54–56} The disulfide radical anion generated by this process reacts rapidly with O_2 via electron transfer to give the disulfide and $O_2^{\bullet-}$ (reaction 22).^{15,54–56} Thiyl radicals dimerize rapidly and can thereby generate inter- or intramolecular protein cross-links. These radical–radical reactions may be severely limited by steric and electronic factors (see **Radical-Based Damage of Sulfur-Containing Amino Acid Residues**).^{54–56}

The thioether group ($R-S-R'$) function of Met residues is readily and rapidly oxidized by many species due to its low oxidation potential (cf. data in Table 4). The major product that arises from oxidation of this residue in most peptides, or proteins, is the corresponding sulfoxide (reaction 23); further oxidation of this species gives the sulfone, although this occurs to a much lesser extent. The

sulfoxide is the major product with a wide range of oxidants regardless of whether the initiating species is a radical or a two-electron oxidant, although the mechanism(s) by which this species is formed are different. Two stereoisomers are generated from the sulfoxide group—the *S* (D-) and *R* (L-) epimers, with this having important ramifications for the repair of this product inside cells as the enzymes (Msrs) responsible for reduction are stereospecific (i.e., each enzyme only reduces specific stereoisomers). The ratio of these isomeric products varies between different oxidants, and also between different Met residues on proteins, with the protein structure being an important controlling factor. Whether this is true *in vivo* is more difficult to ascertain as repair and protein turnover will affect the population present at any particular time.

With powerfully oxidizing radicals, such as $HO^\bullet$, the initial product formed is a transient $R-S^\bullet(OH)-R$ (hydroxy sulfuranyl) adduct. This adduct undergoes rapid further reactions to give the sulfoxide, with this occurring via multiple pathways. In some cases, loss of HO^- yields a monomeric radical cation; this can dimerize to give a dimeric radical-cation with a two-center, three-electron bond. The monomer radical-cation can react with superoxide radicals to give the sulfoxide or be stabilized by other nucleophiles (e.g., amine, hydroxyl, halide, and carboxyl groups) with the resulting formation of short-lived species containing S–N, S–O, and S–halide two-center, three-electron bonds. The formation of these species is dependent on the neighboring residues and peptide sequence. Limited oxidation is also seen at the C–H bonds flanking the sulfur atom with these yielding carbon-centered radicals that undergo typical carbon-centered radical reactions (see above).

4.6 Radicals Derived from Aromatic Side Chains

Reaction of initiating radicals with aromatic side chains (Trp, Tyr, and Phe) and related species (His) occurs predominantly by either addition of a radical to the ring or by electron transfer from the ring to the radical. The latter results in a (usually transient) radical-cation, which usually undergoes rapid deprotonation to yield a neutral species (a phenoxyl radical from Tyr or an indolyl from

Trp). Direct hydrogen abstraction from the ring or methylene ($-\text{CH}_2-$) side-chain groups are minor processes. Reaction of $\text{HO}^\bullet$ with Tyr residues occurs primarily via the formation of substituted cyclohexadienyl adduct. These rapidly eliminate water, in both acid- and base-catalyzed reactions, to give phenoxyl radicals (reaction 24) or react further to give 3,4-dihydroxyphenylalanine (DOPA).^{52,53,129} In the absence of O_2 , DOPA is formed via disproportionation of two ring-derived radicals (reaction 25), whereas in the presence of O_2 , peroxy radical formation is followed by rapid elimination of $\text{HOO}^\bullet$ (reaction 26).^{130,131} The latter pathway yields higher levels of DOPA (one per initial ring radical), whereas in the absence of O_2 , two initial ring-derived radicals yield one DOPA. This material, as well as many other aromatic radical oxidation products (Table 8), has been used as a biomarker of oxidative damage *in vivo*.

Tyr phenoxyl species are generated efficiently and rapidly by a wide range of radicals, due to the ease of ionization of the ring, and also via a range of enzymatic reactions (e.g., peroxidase- and heme protein-mediated processes).^{132,133} Phenoxyl radicals dimerize rapidly (k circa $5 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$),

Table 8 Stable and unstable products formed on oxidation of aromatic amino acids and protein side chains.

via carbon–carbon bond formation, to yield hydroxylated biphenyls (dityrosine; reaction 27).^{134–136} Carbon–oxygen linkages have also been characterized (reaction 28).¹⁰² Addition of O_2 to a phenoxyl radical is slow ($k < 1 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$), and hence, dityrosine yields are usually not significantly affected by the O_2 concentration, unless this alters the initial chemistry of radical formation.^{104,137} In contrast, reaction with $\text{HOO}^\bullet/\text{O}_2^{\bullet-}$ is fast¹⁰⁴ with this resulting in the formation of multiple hydroperoxides at different ring positions; the nature and subsequent reactions of some of these species have been characterized.^{104,138–142} Owing to their considerable lifetime, when dimerization is prevented for steric

or electronic reasons, Tyr phenoxyl radicals can undergo hydrogen or electron transfer reactions with other biological molecules, with this resulting, for example, in the initiation of lipid peroxidation and antioxidant depletion.^{143–151}

Tryptophan-derived ring radicals are also formed in a facile manner due to the ease of oxidation of indole moiety. Addition can occur at either the benzene ring (circa 40%) or the pyrrole moiety (circa 60%) in the case of $\text{HO}^\bullet$ (Scheme 1).^{152–154} In the absence of O_2 , the ring-derived radicals give rise to low yields of hydroxylated products on the benzene ring (4-, 5-, 6-, and 7-hydroxytryptophans; Scheme 1) or lose H_2O to give the neutral indolyl radical (25–30% for $\text{HO}^\bullet$, Scheme 1).^{152,153,155,156} In the presence of O_2 , peroxy radicals are formed on the six-membered ring, some of which (circa 30%) eliminate $\text{HOO}^\bullet/\text{O}_2^{\cdot-}$ to give hydroxylated products. Indolyl radicals react slowly with O_2 to give a peroxy radical (at C3),^{157,158} but this can be a significant process in proteins where this species is isolated and cannot readily undergo other reactions.^{143,146,148,149,159–163} This peroxy species can undergo hydrogen atom/electron transfer reactions to give a hydroperoxide, or undergo further reactions, which result in opening of the pyrrole ring with formation of *N*-formylkynurenine

Scheme 1

Scheme 2

(Scheme 1).^{153,154,164} In contrast to the slow reaction with O_2 , reaction of these indolyl radicals with $HOO^{\bullet}/O_2^{\bullet-}$ is fast ($k = 4.5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) yielding a hydroperoxide (Scheme 1).^{154,158,165}

The chemistry of radical reactions with His is complex and still not completely resolved. $HO^{\bullet}$ undergoes addition to the imidazole ring of histidine at C2, C4, and C5 (Scheme 2),^{166–169} with the resulting adduct radicals either undergoing addition reactions with O_2 (to give peroxy radicals) or base-catalyzed loss of H_2O to give stabilized diazacyclopentadienyl radicals.^{166,168} The final products, and yields, of these reactions have not been determined completely, but include 2-oxo-histidine, asparagine, aspartic acid, hydroxylated derivatives, and hydroperoxides.^{170,171}

Electron transfer reactions occur readily with aromatic side chains, resulting in formation of radical-anion and radical-cation. Addition of an electron to Phe generates a transient radical-anion, which rapidly protonates to give a cyclohexadienyl radical (reaction 29).¹⁷² Radical-cations can be generated from each of the side chains by powerful oxidants¹⁰⁵ and also by photo-ionization (see the following sections). The charge on these species is rapidly lost by processes including hydration (and hence hydroxylated products, reaction 30) and

(29)

(30)

deprotonation from an adjacent C–H (Phe), N–H (with His or Trp), or O–H bond (with Tyr).^{127,173}

4.7 Backbone Radical Chemistry

Hydrogen atom abstraction from the α -carbon position can account for >90% of initial $HO^{\bullet}$ radicals with Ala-containing homopeptides, with this rationalized in terms of the greater stability of the α -carbon species over the primary alkyl radical arising from methyl side-chain hydrogen atom abstraction. This however appears to be an extreme case, with the yield of backbone-derived carbon-centered radicals being much lower when reactive side chains are present.

α -Carbon-centered radicals can also be formed from solvated electron reaction with backbone carbonyl groups (reaction 31).^{174–176} These species, when formed in the middle of peptide chains in the absence of O_2 , decay primarily via reaction with other radicals, with this resulting in the repair of both species (reaction 32).¹⁷⁷ Electron transfer can also occur with electron acceptors, such as cystine (reaction 33) or His residues.¹⁷⁸ Backbone cleavage (reaction 34) is believed to be a minor process.^{179,180}

In the absence of O_2 , α -carbon radicals decay primarily by dimerization,¹⁸¹ with the resulting products characterized for some small peptides. These data indicate that cross-links are formed at all radical sites.^{57,181} With larger peptides, significant side-chain cross-links are also observed.

In the presence of O_2 , backbone peroxy and alkoxy species are formed, which undergo a complex series of reactions that result in backbone cleavage (reviewed in Refs 6, 16, 182). The peroxy radicals have been reported to rapidly eliminate $HOO\cdot$ to give imines that then undergo hydrolysis to the corresponding amides and carbonyl compounds. Studies on cyclo(Gly)₂ and cyclo(Ala)₂ have shown that these reactions are slow at neutral pH values and yield two major product species (Scheme 3). At higher pH, ionization of the $-NH$ group (pK_a 10.8 and 11.2 for cyclo(Gly)₂ and cyclo(Ala)₂, respectively) results in rapid base-catalyzed elimination of $O_2^{\cdot-}$ to give a single product (Scheme 4). The rate of water addition to imines is structure dependent with the $C=N$ bond from cyclo(Gly)₂ reacting with

H_2O approximately 100-fold faster than that from cyclo(Ala)₂.¹⁸³ It is clear from these data that the structure of these species can have a major influence on the rate of backbone hydrolysis.

α -Carbon peroxy radicals can also yield α -carbon hydroperoxides and alkoxy radicals via hydrogen atom abstraction and cross-termination reactions with $O_2^{\cdot-}$ and $HOO\cdot$, respectively.¹⁸⁴ Decay of such hydroperoxides (e.g., catalyzed by metal ions or UV light) yields further alkoxy radicals.^{107,108} These alkoxy radicals undergo β -scission reactions that result in the formation of carbonyl groups and acyl radicals ($\cdot C(O)NHR$) when present at mid-chain sites.¹⁰⁸ This results in cleavage of the backbone. C-terminal alkoxy radicals release $CO_2^{\cdot-}$ or $\cdot C(O)NH_2$ in the case of C-terminal amides (reaction 35). Recent studies indicate that this reaction competes with the peroxy radical/imine/hydrolysis pathway to backbone fragmentation outlined above.^{6,16,182} The contribution of these two pathways to protein backbone fragmentation is yet to be determined,

Scheme 3

Scheme 4

although fragments with new N-termini (cf. the blocked N-termini formed in the imine pathway) have been detected on peptides generated from oxidized proteins. These materials may be alkoxyl radical pathway products, as acyl radicals can give rise to isocyanates (via addition of O₂ and loss of HOO[•]) at the new N-terminus which readily hydrolyze to the amine plus CO₂.^{81,185–187} Fragments consistent with the alkoxyl radical pathway have also been detected during backbone cleavage of the R1 subunit of ribonucleotide reductase, where a backbone, Gly-derived, α -carbon radical is involved.¹⁸⁸

4.8 Radical Translocation Between Sites in Proteins

Some of the data reviewed above are consistent with radical transfer reactions occurring between sites in proteins. Transfer between side-chain sites in peptides and proteins is particularly well characterized, and primarily involves aromatic and sulfur-containing residues. These reactions have yielded important information about mechanisms and pathways of transfer of oxidizing equivalents and electrons through proteins (reviewed in Refs 179, 189–191, see also **Electron Transfer in Peptides and Proteins**). The reduction potentials of peptide radicals indicate that the ultimate sink for oxidizing equivalents in proteins are Tyr and Cys residues (or Trp in the absence of these side chains).¹⁸⁹ Some of these reactions are near equilibrium and hence are readily reversible. Thus, Tyr phenoxyl radicals can be generated by thiyl radicals and also repaired by Cys reactions,^{189,192} with the balance of this process modulated by excess thiolate anions, as thiyl radicals can be removed via reaction with these species (to give the disulfide radical anion).

Oxidation of Trp residues can, as outlined above, yield the nitrogen-centered indolyl radical. However, if such species are generated on proteins that also contain Tyr residues, rapid electron

transfer occurs between these species to yield the Tyr phenoxyl radicals over a millisecond timescale.^{179,190} Such transfer can occur over long distances in proteins, but the rate of transfer is very much dependent on the peptide/protein structure. Slow transfer can be observed even if the residues are close in distance, if they are held in an unfavorable rigid conformation.¹⁹³ In contrast, rapid transfer can occur over very long distances if the structure is flexible or if there are suitable intervening residues that can act as a conduit for electron migration.^{189,193,194} In many proteins, the transfer pathway is unclear due to the presence of multiple Tyr and Trp residues and hence alternative pathways. Transfer reactions have also been demonstrated between a number of other residues.¹⁸⁹ These types of reactions may result in a different pattern of oxidation, and kinetics of these processes, than that might be initially expected on the basis of the reactivity of the initiating radical alone.¹⁸⁹

The disulfide bond of cystine (and hence O₂ as a result of rapid electron transfer from the disulfide anion radical) is a major sink for electrons and reducing equivalents. Electron migration to disulfide bonds can compete with direct addition to O₂ in some cases.¹⁷⁹ In this case, transfer is believed to occur via hydrogen bonding networks, with the backbone acting as an efficient conduit, unlike the oxidative pathway.^{191,195} The formation of disulfide radical-anions can be of particular importance as thiyl radicals can be generated from these species via the reverse of reaction 21. The thiyl radicals can, in turn, oxidize Tyr residues, thereby providing a point of convergence of the oxidative and reductive pathways. Studies with chemically modified metalloproteins with a reactive metal ion at a defined surface site have provided some information about the mechanism and control of electron transfer within proteins.^{196,197}

Damage transfer occurs readily in heme proteins where the initial oxidation occurs at the heme moiety. Reaction of H₂O₂ and other two electron oxidants with Fe³⁺ forms of heme proteins (e.g., hemoglobin, myoglobin, and leghemoglobin) gives rise to protein (globin) radicals via the generation of a Fe⁴⁺-oxo (ferryl) porphyrin radical-cation (reaction 36) and subsequent repair of this species by electron transfer from protein residues (reaction 37; predominantly Trp and Tyr residues; reviewed in Refs 24, 198).

Tyr-, Trp-, His-, and other carbon-centered radicals have been detected as a result of these types of reaction, and it is clear that this is a widespread process. The yield of these radicals appears to be significant in some cases, for example, with hemoglobin, myoglobin, and leghemoglobin, but much lower in “professional” peroxidases that deliberately generate such high oxidation state (compound I) species. The pathways by which these protein radicals are formed are not fully defined in all cases, and it is clear that multiple pathways (and hence residues oxidized) can occur in the same protein (cf. evidence for formation of multiple Tyr- and Trp-derived radicals in myoglobins discussed above). Some of these radicals are likely to be in equilibrium making the analysis complex. Site-directed mutagenesis studies have shown in myoglobins that removal of all the Tyr residues still results in radical formation, suggesting that the removal, or blocking of a key pathway, merely switches the site of oxidation to another available residue. In some cases, protein structure appears to play a key role, with Trp-14 being a major site in myoglobin, even though this is more distant from the oxidized heme than an alternative Trp residue (Trp-7); this has been rationalized in terms of the orientation of these residues to the porphyrin ring.^{161,199,200} The subsequent chemistry of some of these radicals has been elucidated, with evidence presented for the formation of intermolecular (protein–protein) cross-links, as well as heme–protein cross-links, and oxidation of other targets (e.g., thiol, Tyr, and Trp groups on other proteins, antioxidants, and lipids^{148,149,201–207}).

Evidence has also been obtained (see above) for radical transfer from side-chain sites to the α -carbon and occasionally for the reverse (predominantly with Cys) residues. The paucity of the latter processes is as expected in the light of the known stability of α -carbon radicals. Repair of α -carbon species by external thiols has been studied extensively as a means of protection against radiation damage.¹⁰⁵ A thiyl radical generated from the Cys residue in

reduced glutathione (GSH) can abstract a hydrogen atom from a suitably placed backbone α -carbon site (reaction 38).^{208–210} This process occurs readily, unlike most hydrogen abstraction reactions by thiyl radicals (the reverse reaction—repair—is usually favored), due to the stability of the α -carbon radical. Thus, reaction 38 occurs with GSH at pH values where the γ -glutamyl amine function is deprotonated, even though this involves a nine-membered transition state.²⁰⁹ Analogous thiyl to α -carbon transfer occurs with the thiyl radical from homocysteine when the amino group is deprotonated.²¹¹ Recent studies have also indicated that such transfer occurs with Cys despite this (apparently) involving a 1,4 rearrangement.^{212–214}

5 REACTION OF PEROXYNITRITE AND OTHER REACTIVE NITROGEN SPECIES WITH PROTEINS

NO• is generated from the amino acid arginine by nitric oxide synthase enzymes, which are widely expressed in multiple cells (e.g., endothelial, macrophage, and neuronal, reviewed in Refs 215, 216). NO• modulates a wide range of diverse biological processes including vascular tone, proliferation, and aggregation.²¹⁵ While this species has undoubted beneficial effects, high levels of NO• have been linked with cellular damage, continued inflammation, and apoptosis as a result of its rapid reaction ($k \sim 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ ²¹⁷) with superoxide radicals ($\text{O}_2^{\bullet-}$) to generate peroxynitrite,²¹⁸ a process that can compete successfully with the removal of $\text{O}_2^{\bullet-}$ by SOD enzymes ($k \sim 10^9 \text{ M}^{-1} \text{ s}^{-1}$ ²¹⁹) when the flux of NO• is high.²¹⁷

Peroxynitrite can induce considerable biological damage, through the species and chemistry involved is complex. Multiple studies have provided evidence for damage by ONOOH itself, by HO $\cdot$ and NO $_2\cdot$ formed from the homolysis of this species (in yields of circa 30%²¹⁷), by an adduct species, ONOOCO $_2^-$ (formed with physiological concentrations of CO $_2$), and by NO $_2\cdot$ and CO $_3^{\cdot-}$ formed from the latter (in yields of circa 35%²¹⁷). The reactions of the radicals formed from both ONOOH and ONOOCO $_2^-$ are covered above, and the discussion below is therefore focused on the molecular reactions of these oxidants. Considerable evidence exists for damage primarily at side-chain sites, with Cys, Met, and Trp reacting directly with ONOOH, and Tyr, His, and Phe also being modified, predominantly as a result of secondary reactions. Kinetic data on the reactions of ONOOH with proteins and free amino acids have been reviewed.²²⁰

Reaction with Cys residues has been shown to generate a wide range of products, including cystine, sulfenic, sulfinic and sulfonic acids, nitroso-cysteine (RSNO), nitrocysteine (RSNO $_2$) as well as thiyl, sulfinyl, and disulfide anion radicals.^{5, 221–226} The formation of the radical species clearly involves one-electron chemistry, and there is some evidence for the formation of nitrosocysteine and nitrocysteine likewise (i.e., the formation of the latter materials is likely to involve termination reactions of thiyl radicals with nitric oxide and NO $_2\cdot$ radicals, respectively), although evidence has also been presented for a direct reaction of ONOOH with Cys to yield RSNO.²²⁴ The formation of the disulfide, cystine, has been reported to occur via a direct nucleophilic attack of the thiolate anion on ONOOH, with this giving the sulfenic acid and nitrite as initial products. Subsequent reaction of the sulfenic acid with an additional molecule of Cys yields cystine. The higher rate constants for reaction of ONOOH with some Cys residues on proteins (for rate constants see Ref. 220) is therefore explicable in the light of the varying pK $_a$ values for the Cys residues on these proteins. The cystine formed from this reaction does not appear to have any significant reactivity with ONOOH (cf. the absence in any change in the rate of decay of ONOOH in the presence of this species²²⁷), but reaction does appear to occur with the more reactive disulfide of lipoic acid with this resulting in formation of the corresponding disulfide S-oxide.²²⁷

Peroxynitrite reacts rapidly with Met residues to give both sulfoxide and ethylene (ethene). These products may arise via three possible processes. The first of these involves the formation of radical reactions of HO $\cdot$ and NO $_2\cdot$ from decomposition of ONOOH. The second mechanism is via direct reaction of ONOOH with Met, probably via the formation of an initial adduct species, R–S $^+$ (OH)–R, with release of NO $_2^-$, and subsequent deprotonation of the former to give the sulfoxide, and the third is via peroxynitrite anion addition to the sulfur function and subsequent decomposition of this species to the sulfoxide. Of the latter two pathways, the one involving ONOOH appears to be more rapid than that involving ONOO $^-$.^{228, 229} Studies with materials that react rapidly with HO $\cdot$ have reported only marginal effects on the yields of sulfoxide and ethylene, consistent with radicals being only minor contributors.²²⁸ The ONOOCO $_2^-$ adduct appears to oxidize Met at a much slower rate than ONOOH or ONOO $^-$, suggesting that Met oxidation *in vivo* is modulated to a major extent by CO $_2$ levels.^{230, 231}

Trp residues react directly with ONOOH relatively slowly²³² ($k \sim 40 \text{ M}^{-1} \text{ s}^{-1}$), whereas the corresponding reactions of the radicals derived from ONOOH and ONOOCO $_2^-$ are very rapid. The formation of radical species has been confirmed by electron paramagnetic resonance (EPR) spin trapping.^{233–236} As such, a mixture of products is typically observed. These include radical oxidation products (hydroxytryptophan, *N*-formylkynurenine, hydropyrroloindole, and oxindole; see above) mentioned above and 5- and 6-nitrotryptophan. The yield of both the direct and radical products has been reported to be enhanced by the presence of CO $_2$ and hence the formation of ONOOCO $_2^-$.^{232, 233}

Reaction of ONOOH with Tyr does not appear to occur via direct reaction, but to predominantly occur via a radical mechanism, as the presence of this amino acid does not modulate the direct decay kinetics of ONOOH.^{220, 232} Reaction appears to occur via radical formation from either ONOOH or ONOOCO $_2^-$, with this giving rise to a Tyr phenoxyl radical (either via direct hydrogen atom abstraction or via an initial ring adduct; see above). Subsequent reactions of this species include formation of dityrosine and DOPA, as outlined above, and reaction with NO $_2\cdot$ to give 3-nitrotyrosine.^{237–244} This last species has been used extensively as a biomarker of peroxynitrite formation, although other

processes that give rise to phenoxyl radicals and $\text{NO}_2^\bullet$ (e.g., peroxidase-induced oxidation of Tyr and NO_2^-) may complicate the interpretation of the *in vivo* data.²⁴⁵ $\text{NO}_2^\bullet$ is not a very reactive radical²⁴⁶ and appears to require a cogeneration system to generate the Tyr phenoxyl radical to result in significant yields of 3-nitrotyrosine. The presence of CO_2 can enhance the usually low yield of 3-nitrotyrosine (which is typically $<10\%$ ²²⁰), as the $\text{CO}_3^{\bullet-}$ formed from the adduct species markedly enhances the yield of phenoxyl radicals from Tyr,²⁴⁷ as it shows a greater propensity for direct hydrogen atom abstraction from the $-\text{OH}$ bond on the ring. Phenylalanine is also oxidized by ONOOH to give nitrated products but again this appears to be a radical mediated process, as judged by the detection of *o*- and *m*-Tyr in addition to nitrophenylalanine; the former are typical $\text{HO}^\bullet$ products.²⁴⁸ Nonetheless, the detection of nitrophenylalanine has been used to invoke the formation of peroxynitrite *in vivo*.²⁴⁹

6 REACTION OF HYPOCHLOROUS, HYPOBROMOUS, AND HYPOTHIOCYANOUS ACIDS AND RELATED N-HALO SPECIES WITH PROTEINS

HOCl , HOBr , and hypothiocyanous acid (HOSCN) are generated by the heme peroxidase myeloperoxidase (MPO) released from activated neutrophils, monocytes, and tissue macrophages. This enzyme uses H_2O_2 generated by multiple cells to catalyze the oxidation of Cl^- , Br^- , and SCN^- to these powerful oxidants (reviewed in Refs 250–254). The analogous eosinophil-derived species, eosinophil peroxidase (EPO) generates HOBr and HOSCN , but not HOCl .^{255–260} HOCl and HOBr are both strong oxidants and capable of halogenation reactions.

HOCl and HOBr react avidly with sulfur and nitrogen atoms, such as those present in thiols, thioethers, amines, and amides; Cys and Met residues in proteins are therefore key targets for HOCl and HOBr .^{261–265} Oxidation of Cys by HOCl yields a sulfenyl chloride (RS-Cl), which undergoes rapid reaction with excess thiol, to give the disulfide²⁶¹ or water to yield sulfenic (RSOH), sulfinic (RSO_2H), or sulfonic (cysteic acid, RSO_3H) acids (reviewed in Ref. 266). Cystine can be oxidized to sulfonic acids via S-chlorinated and

S-oxygenated intermediates (reviewed in Ref. 266). HOCl can also induce the formation of sulfenamide (RSNR'), sulfinamide ($\text{RS(O)NR}'$), and sulfonamide ($\text{RS(O)}_2\text{NR}'$) cross-links in peptides (e.g., GSH) and proteins,^{267–270} via nucleophilic attack of Lys or Arg side chains on RS-Cl , sulfenic, or sulfinic acid intermediates.

The high susceptibility of Cys residues to oxidation by hypohalous acids has important implications for cells, as a number of key cellular enzymes have Cys residues in their active sites. Thus, creatine kinase and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) are readily inactivated by HOCl , with the loss of activity correlating with thiol depletion.^{265,271} Conversely, HOCl can activate the (inactive) pro-forms of matrix metalloproteinases (e.g., MMP-7) via conversion of a key Cys residue in the cysteine switch domain of pro-MMP-7 to a sulfinic acid derivative.²⁷²

Oxidation of Met side chains results in the formation of Met sulfoxide (and with very large excesses of oxidant to Met sulfone),^{273,274} with this resulting in potential impairment of protein function and inactivation of enzymes (e.g., lysozyme and α_1 -antiproteinase^{273,275–278}). In other cases, such as with soybean trypsin inhibitor, Met oxidation did not correlate with loss of function despite the related structure and similar active site of this species to α_1 -antiproteinase.^{273,275} Recent studies have also shown that Met residues can be oxidized to dehydromethionine on peptides when this residue is present at the N-terminus.²⁷⁹

Nitrogen-containing functional groups, particularly amines and to a lesser extent amides, are readily converted to N-chlorinated and N-brominated species by HOCl/HOBr .^{253,260,280–283} The amine-derived species are generically known as halamines (chloramines, $\text{RR}'\text{NCl}$; bromamines, $\text{RR}'\text{NBr}$), while those species formed from amides are halamides (chloramides, RC(O)N(R')Cl ; bromamides, RC(O)N(R')Br). For primary halamines (where $\text{R}' = \text{H}$), further reaction with HOCl and HOBr yields dichloramines (RNCl_2) or dibromamines (RNBr_2). With chloramines, dichloramine formation only occurs to an appreciable extent when there is a large excess of HOCl over amine.^{260,280,281,284,285} However, with bromamines, rapid equilibration reactions can occur that result in dibromamine formation, even when the amine is present in large excess.²⁶⁰

Halamines and halamides can be generated on a wide variety of biological substrates. Free amino acids yield halamines on the α -amino group, and in cases such as Lys, His, and Arg where the side chain features a nucleophilic nitrogen center, halamines are also generated at these sites.^{7,253,260,281–283,286–291} Incorporation of amino acids into proteins results in derivatization of the α -amino group with halamine formation on proteins therefore restricted primarily to His, Lys, and Arg side chains, together with the N-terminal amino group. Halamide formation can occur at backbone peptide (amide) bonds with high excess of hypohalous acids, and the amide-containing side chains of Gln and Asn can also be converted to halamides.²⁹¹

Other small molecules that contain an amino residue, and are abundant *in vivo*, can also form halamines. Thus, the sulfonated β -amino acid, taurine, has been postulated to act as a cellular defense mechanism against hypohalous acid production by reacting rapidly with HOCl and HOBr to give long-lived intermediates.²⁸² However, taurine halamines are also capable of inducing further oxidation and hence detrimental cellular effects.^{271,292}

It is clear from these data that halamines and halamides are the key products of HOCl/HOBr reactions with a wide range of biological molecules. These halamines/amides retain the oxidizing capacity of the parent oxidant and can induce further reactions, some of which regenerate the parent amine as a result of halogen transfer or radical reactions, while others result in modification of the amine group. One major pathway is hydrolysis, which yields aldehydes, probably via imine intermediates (reaction 39).^{287,290,291,293–295} Aldehyde formation from bromamines occurs more readily than that from the corresponding chloramines.^{275,291,296,297} The resulting carbonyl species can react with protein or lipid amine groups to generate Schiff base imines, which can ultimately yield advanced glycation end products; the latter have strong links to vascular disease.^{298,299} Hydrolysis of His side-chain chloramines is a potential pathway for the formation of 2-oxo-His.²⁹¹

Halamines and halamides can decompose via radical pathways, with these reactions promoted by

low-valent redox-active metal ions (Fe^{2+} and Cu^+) and $\text{O}_2^{\cdot-}$. These processes yield nitrogen-centered radicals ($\text{RNH}^\cdot$)^{100,300–306} that can undergo a range of intra- and intermolecular reactions resulting in further oxidative damage (reviewed in Ref. 291).

As halamines and halamides retain the oxidizing capacity of the hypohalous acid from which they are generated, they are potentially capable of mediating cellular damage. Thus, evidence has been presented for halamines, rather than HOCl/HOBr, being major mediators of toxicity as they are long-lived species that can diffuse through cellular membranes and hence mediate oxidative damage at remote locations away from their site of generation. Halamines are capable of oxidizing thiols and thioethers, such as Cys and Met, as described above for the parent hypohalous acids,^{271,284,285,292,307,308} although halamines do not appear to produce the diversity of products observed with HOCl and HOBr. Thus, only sulfonic acids and disulfides have been detected on oxidation of thiols by halamines, with no evidence for the formation of glutathione sulfonamide.^{270,309} Halamines and halamides display a far greater selectivity in their reactions than the hypohalous acids, with low $\text{p}K_a$ thiols (e.g., those present in some enzymes) particularly susceptible to oxidation by chloramines.²⁷¹ Halamines have been shown to modulate apoptotic pathways,^{310,311} inactivate intracellular enzymes,^{271,281,311} and induce cell death.^{271,281,311}

In addition to reactions with nucleophiles, HOCl and HOBr also react with aromatic rings and double bonds, including some amino acids (Tyr and Trp), nucleobases, and fatty acid side chains (reviewed in Refs 291, 312). Similar reactions also appear to occur with chloramines and bromamines, although at slower rates and with lower efficiency. Reactions with the phenolic side chain of Tyr are of particular importance as these reactions result in the formation of 3-chlorotyrosine (3-chloro-Tyr) and 3-bromotyrosine (3-bromo-Tyr). With large excesses of oxidant, these products are further halogenated to form 3,5-dichlorotyrosine (3,5-dichloro-Tyr) and 3,5-dibromotyrosine (3,5-dibromo-Tyr). These compounds constitute the only known specific biomarkers for HOCl-, HOBr-, or halamine-mediated damage to proteins.^{254,291,312–319} A number of studies have demonstrated that halamines are important intermediates in the formation of these materials on isolated proteins,^{316,320}

although they are also formed via direct reactions with HOCl and HOBr, respectively.³²¹

Trp oxidation by HOCl yields the 2-oxindole, possibly via an initial 3-chloroindole adduct and subsequent hydrolysis;^{322–326} this product may also be generated by HOBr and halamines.²⁷⁴ Recent studies have shown that the products formed on oxidation of Trp in peptides or proteins depend on the local sequence, with a cyclized product detected when the neighboring residue is a Gly or Ala residue,^{326,327} with other side chains, mono- or dioxxygenated derivatives of Trp are formed. Whether analogous products are formed with HOBr remains to be established.

MPO, EPO, and LPO are all also capable of converting SCN[−] into HOSCN.^{256,257,328–330} This species can also be generated by direct reaction of HOCl or HOBr with SCN[−],^{331,332} and it has been suggested that the majority of HOBr generated under physiologically relevant conditions is converted to HOSCN.³³²

Product studies indicate that HOSCN is much more selective than HOCl and HOBr, with strong evidence that the major target for HOSCN is thiols (either on proteins or low-molecular mass species such as GSH).^{328,333–335} The primary products of reaction of HOSCN with thiols are RS-SCN species and disulfides; the RS-SCN adducts can react further (e.g., hydrolysis to sulfenic acids) or be repaired by reductants.^{328,334,335} There is limited evidence for damage to other targets such as aromatic residues, with modification of Tyr, His, and Trp detected following exposure of proteins and polypeptides (particularly those without Cys residues) to SCN-derived oxidants.³³⁵ It has been postulated that these reactions occur via addition of SCN⁺ from (SCN)₂ to the aromatic ring, rather than via reaction of HOSCN.³³⁵ It has also been suggested that RN-SCN species are generated with imidazole groups such as His,³³⁶ and recent studies have confirmed that HOSCN can modify Trp residues.³³⁷

Exposure of proteins to SCN-derived oxidants has been shown to result in the loss of Lys residues and the formation of carbamylated Lys derivatives (RN-C(O)NH₂).³²⁸ These products are formed via the irreversible addition of the HOSCN decay product, [−]OCN, to the Lys amine group.³²⁸ Reagent [−]OCN, and that formed via the decomposition of urea, reacts similarly and has also been shown to target other (nucleophilic) moieties such as

the α -amino groups of amino acids, peptides and proteins, and (reversibly) thiol groups.³³⁸

Although HOSCN is a much less powerful oxidant than HOCl and HOBr, there is considerable evidence that this species can exert considerable biological damage as a result of its greater specificity, particularly for thiols. Kinetic studies have shown that HOSCN reacts with both low-molecular-mass and protein thiols with rate constants in the range 10⁴–10⁶ M^{−1} s^{−1}; reactions with other amino acids were too slow to be monitored (i.e., $k < 10^3$ M^{−1} s^{−1}).^{8,339} SCN-derived oxidants, believed to be HOSCN, can inactivate a range of thiol-containing enzymes (e.g., GAPDH, glutathione-S-transferases, and membrane ATPases)^{257,328,333,340} and deplete intracellular GSH.^{341,342} It has been shown that HOSCN inactivates membrane ATPases 10–1000 times more effectively than HOCl and HOBr due to this enhanced selectivity for critical thiols.³²⁸ Exposure of endothelial cells to HOSCN has also been shown to induce tissue factor activity and promote expression of cell adhesion molecules, with these effects postulated to be due to specific oxidation of redox-sensitive thiols and resulting activation of NF- κ B.^{343–345} If this mechanism is correct, it would be expected that a large number of genes would be upregulated following exposure of cells to HOSCN.³⁴⁵ Recent studies support this suggestion with HOSCN shown to oxidize thiol groups on protein tyrosine phosphatases (which control cellular tyrosine phosphorylation levels) with a resulting loss of enzyme activity.³⁴⁶ This results in hyper-phosphorylation of cellular proteins, activation of the mitogen-activated protein kinase (MAPK) pathway, and enhanced apoptosis.^{341,346}

7 PHOTO-OXIDATION OF PROTEINS

Proteins are major targets for photo-oxidation within cells due to the presence of endogenous chromophores within some protein structures (both amino acid side chains and bound prosthetic groups such as flavins and heme), their ability to bind exogenous chromophoric materials, and their rapid rates of reaction with other excited state species. Photo-oxidation occurs via two major routes: direct photo-oxidation arising from the absorption of UV radiation by the protein structure (primarily side chains) or bound chromophores, thereby generating

excited state species (singlet or triplets) or radicals as a result of photo-ionization (type 1 processes) and secondly via the formation and subsequent reactions of singlet oxygen (molecular oxygen in its first excited singlet state, $^1\Delta_g$ O₂, or 1 O₂) generated by the transfer of energy to ground state (triplet) molecular oxygen by either protein-bound or other chromophores (type 2 processes).²¹

Direct oxidation of amino acids, peptides, and proteins by UV light is only a significant process if the incident light is absorbed by the protein. For most proteins without bound (covalent or noncovalent) cofactors or prosthetic groups, this only occurs with light with $\lambda \leq$ circa 320 nm. The major chromophoric amino acids present in proteins are Trp, Tyr, and Cys with the wavelengths of UV light that reach the surface of the earth. The direct photochemistry of proteins is therefore dominated by these amino acid side chains, with the contribution of each side chain depending on their abundance. The indolic side chain of Trp has the longest wavelength ground-state absorption spectrum and also has a significantly greater molar absorption coefficient for each of its major absorption bands than the other species; it is therefore the most significant chromophore in many proteins. This significance is however tempered by the lower abundance of this side chain in many proteins.

7.1 Direct (Type 1) Photo-Oxidation

The absorption of UV light by Trp, Tyr, and cystine can give both excited states and radicals via photo-ionization. The major initial species are usually in the first excited singlet state, but these are typically short lived, and readily lose energy via direct energy transfer to other groups, by collisional deactivation and vibrations, and via inter-system crossing to the triplet state. As such, most protein singlet states react via energy transfer rather than chemical reaction. The relative energies of the singlet states decrease in the order: Phe > Tyr > Trp, which can result in rapid energy transfer from Phe and Tyr to Trp; this results in the fluorescence spectra of most proteins being dominated by Trp.

The triplet states of Trp and Tyr have been studied extensively as these are longer lived than the singlets and show chemical reactivity (i.e., can undergo electron, as well as energy, transfer reactions).^{347,348} The first triplet states of Trp

and Tyr undergo electron transfer reactions with suitable acceptors such as disulfides (reactions 40 and 41), with this resulting in the formation of the disulfide radical anion and the corresponding aromatic radical-cations.^{347,348} The latter rapidly deprotonate to give the neutral indolyl radical and Tyr phenoxyl radical; the chemistry of these species is outlined above.

The disulfide radical anion ($\text{RSSR}^{\bullet-}$) formed as a result of electron transfer can dissociate, reversibly, to give the anion and a thiyl radical or react with O₂ to give a superoxide radical ($\text{O}_2^{\bullet-}$) and parent disulfide (see above).

^3Tyr can also be quenched by direct electron transfer with O₂ ($k = 4.8 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$), with His (with $k = 7.7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ at pH 7.7—this is a pH-dependent process) and with Cys (with $k = 5.2 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$).^{21,347,348} In each case, ^3Tyr is converted to its phenoxyl radical via the radical-cation and the partner is converted initially to the radical-anion, although these undergo further reactions. The Tyr phenoxyl radical and the Trp indolyl radical are also generated via similar reactions by a wide range of triplet sensitizers (e.g., Ref. 349).

High-energy triplets of other chromophores can also induce direct hydrogen atom abstraction reactions with protein side chains. These reactions usually yield carbon-centered radicals (or thiyl radicals from Cys). These radical reactions have been reviewed.¹⁸²

Direct photo-dissociation of cystine to give two thiyl radicals occurs readily due to the significant absorbance of the disulfide bond between 250 and 300 nm.³⁵⁰ A major fate of such radicals is dimerization (and hence repair of the disulfide bond), but alternative reactions, such as that with O₂ (see above), can result in irreversible oxidation via formation of oxyacids. These reactions can have significant effects on the integrity of proteins, due to the role of disulfide bonds in maintaining tertiary structures. Trp, Tyr, Phe, and His can also undergo direct photo-ionization, although there is controversy in the literature regarding the quantitative significance of mono-versus bi-photon processes in such reactions, particularly when long wavelength UV light is

employed.^{21,347,348} Direct cleavage of the phenolic –O–H bond can occur with Tyr, with this yielding the phenoxyl radical, a proton, and a hydrated electron.²¹ The chemistry of the hydrated electron is well characterized with addition to O₂ to give O₂^{•−}, being very fast (k circa $10^{10} \text{ M}^{-1} \text{ s}^{-1}$).³⁵¹ Electron attachment can also occur to free carboxyl groups (e.g., the C-terminus or Asp/Glu side chains) and amine groups (e.g., the N-terminus or Lys side chains) in processes that result in deamination and elimination of H⁺, respectively. Addition can also occur at other sites, particularly with cystine (to give the disulfide radical-anion) and protonated His side chains. In peptides, the hydrated electron can also add to the carbonyl groups of the peptide backbone to give a radical-anion that can subsequently give rise to backbone cleavage. These reactions have been reviewed in Refs 13, 15.

7.2 Singlet Oxygen-Mediated Protein Damage

¹O₂ can interact with protein side chains by both physical quenching and chemical reaction, and rate constants have been determined for many of these reactions.³⁵² The former results in energy transfer and de-excitation of the singlet state but no chemical change in the energy acceptor. For proteins, only Trp appears to give rise to significant physical quenching,³⁵³ with k circa $2\text{--}7 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$; chemical reaction occurs at k circa $3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$.³⁵³ The relative contributions of these processes with Trp is affected by multiple factors, including the environment of the residue and the presence of neighboring reactive residues.^{354,355} The rate constants for chemical reaction of ¹O₂ with the side chains of amino acids vary dramatically with only Trp, His, Tyr, Met, and Cys, undergoing rapid ($k > 1 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$) chemical reaction at physiological pH values. All other side chains react with $k < \sim 10^6 \text{ M}^{-1} \text{ s}^{-1}$ at neutral pH.³⁵², although some of these processes are pH dependent. Thus, at high pH, Arg and Lys react rapidly via their neutral (unprotonated) forms.³⁵⁶

In the case of Trp, Tyr, and His, there is considerable evidence for the initial formation of endo- and hydro-peroxides as a result of the addition of ¹O₂ to these residues. In the case of Trp and Tyr, these peroxides are reasonably well characterized; those formed with His are much less stable and

the exact nature of the (multiple) species formed remains to be completely established.^{357–369}

With free Trp, reaction with ¹O₂ yields 3*a*-hydroperoxypyrroloindole as an isolable product. It has been proposed that the initial species may be a dioxetane across the C2–C3 double bond (Scheme 5),^{367,368} although there is limited direct evidence for this with the free amino acid. Other potential intermediates include a hydroperoxide at C3 (Scheme 5).^{364,370–374} Peptide-bound Trp appears to undergo somewhat similar reactions to that of free Trp, although the ring-closing reaction to give the pyrroloindole appears to be slower due to the incorporation of the nitrogen lone pair into the peptide (amide) bond.³⁵⁹

With free Tyr and peptide-bound Tyr, evidence has been presented for the generation of multiple peroxidic species, although again the initial species, probably an endoperoxide, has not been detected (Scheme 6). Ring opening of the endoperoxide has been proposed to give a hydroperoxide at C1 and direct evidence has been obtained for the presence of both these compounds³⁵⁷ and related species with other phenols.^{362,375} With free Tyr, rapid ring closure involving the nitrogen lone pair of the amine then ensues to give a bicyclic product

Scheme 5

Scheme 6

Scheme 7

3*a*-hydroperoxy-6-oxo-2,3,3*a*,6,7,7*a*-hexahydro-1*H*-indol-2-carboxylic acid, which has been extensively characterized (Scheme 6).^{138,357,358,376,377}

With peptide Tyr residues, a peroxide formed at C1 on the ring has been detected and characterized by nuclear magnetic resonance (NMR).³⁵⁷ This is believed to arise from ring opening of an initial endoperoxide (Scheme 7). The detection of this species with peptide Tyr residues, but not the free amino acid, is believed to result from a longer lifetime of this species as a result of the slower ring closure reaction with the amine group when this is incorporated into the peptide bond.³⁵⁷ With 4-hydroxyphenylpropionic acid where such reactions cannot occur, the C1 peroxide is the major species detected.

Oxidation of free His by $^1\text{O}_2$ is also believed to occur via initial endoperoxide formation and the consumption of a single molecule of O_2 per mole His (Scheme 8).³⁷⁸ Analogous endoperoxides have been detected directly by low-temperature NMR

with highly substituted derivatives in organic solvents.³⁶⁵ Decomposition of these species at elevated temperatures yielded further uncharacterized intermediates, and subsequently, stable products. Studies from the author's laboratory indicate that multiple peroxides are present in reaction mixtures from free His, with these having lifetimes of minutes to hours at room temperature. These species may be hydroperoxides formed by ring opening of an initial endoperoxide by analogy to the behavior detected with Trp and Tyr, respectively. Subsequent decomposition of these materials results in ring opening and the formation of urea, Asn, and Asp as well as other materials (Scheme 8).

Evidence has been presented for the formation of a zwitterionic peroxy species during the photo-oxidation of free Met residues (Scheme 9).³⁷⁹ This species subsequently reacts with a second molecule of Met to give up to 2 moles of sulfoxide.³⁷⁹ The stoichiometry of the latter process

Scheme 8

Scheme 9

is complex and pH dependent, with this being 1 : 1 above pH 7 and 1 : 2 below pH 5; these data suggest that other reactions also occur. Other intermediates including a nitrogen-sulfur cyclic intermediate have been reported (reviewed in Refs 380, 381), with hydrolysis of this species yielding the sulfoxide.³⁷⁹ This intermediate is only likely to be of significance with free Met, due to the involvement of the free amino group, and the situation with Met residues in peptides and proteins remains to be fully elucidated. It is however clear that the sulfoxide is a major product.^{382,383}

As with Met, the products arising from reaction of free Cys are well established (disulfide and oxyacid formation) but the mechanism is less clear.^{380,381,384} The quantitative yield of the products arising from Cys residues in proteins is not well established, and the ratio of disulfide to oxyacids is likely to vary between proteins due to steric or electronic barriers to dimer formation. Qualitative studies have shown that oxidation of free cystine occurs via a zwitterion peroxy intermediate, which reacts further with another molecule of cystine to give two molecules of RSS(=O)R.^{380,385} The effect of incorporation of cystine residues into a protein on such reactions, where steric and electronic effects

are likely to inhibit such subsequent reactions, remains to be determined.

8 CONSEQUENCES OF PROTEIN OXIDATION

Oxidation of proteins has a wide range of downstream consequences and only the general principles are reviewed here briefly. As is obvious from the above sections, oxidation can result in major physical changes in protein structure ranging from fragmentation of the backbone to oxidation of the side chains. The latter can result in either direct, or subsequent, dimerization or aggregation. Direct cross-linking can occur via intermolecular radical-radical dimerization of Tyr phenoxyl radicals to give interprotein di-tyrosine cross-links or thiyl radical termination reactions to give (reducible) disulfides. Secondary dimerization can occur via multiple pathways, including reactions of Lys, Arg, and His residues with carbonyl groups generated by oxidation on other residues, via (uncharacterized) His oxidation products, and from the reaction of quinones (e.g., those generated from DOPA generated from Tyr residues) with nucleophiles (Cys, Lys, Arg, His, and α -amino) on other proteins. The exact nature of these cross-linking reactions, and the species formed, remains to be established.

Oxidation at both backbone and side-chain sites can yield further reactive species. These include endo- and hydroperoxides, chloramines/chloramides and bromamines/bromamides, DOPA (and quinones from further oxidation), and other intermediates such as R-S-X and R-S⁺(X)-R (X = OH, Cl, Br, NO). Decomposition of the peroxides, chloramines/chloramides, and bromamines/bromamides by low valent metal ions, superoxide radicals, or UV light can yield further radicals that may initiate further damage.^{100,107,108,300,302} Reaction of DOPA

formed from Tyr (either the free amino acid or on proteins), with trace metal ions such as Fe^{3+} or Cu^{2+} , can generate semi-quinone radical-anions and hence superoxide radicals (by electron transfer from the radical anion) and H_2O_2 by dismutation.^{109,386} Each of these processes may initiate further damage to the same protein, other proteins, or alternative biological targets.

Oxidation of protein side chains can result in unfolding and conformational changes with these having consequential effects on biological function.³⁸⁷ Oxidation of surface-exposed residues may have more limited effects than oxidation of buried residues, as many of the products of oxidation are more polar than the parent (cf. species in Table 7). This may be counter balanced by a slower rate of oxidation for access reasons, when the oxidant is present in the bulk aqueous phase. There are, however, some notable exceptions, including the decarboxylation of Asp/Glu residues¹⁰⁸ and deamination of Lys residues^{100,388} induced by hydroperoxide decomposition and chloramine decomposition, respectively.

Oxidation of aromatic and Met residues can also result in the incorporation of polar or charged groups (e.g., hydroxyl-, peroxy-, nitro-, chloro-, and bromo-groups, among others, cf. data in Table 8), which will preferentially localize on external, solvent-accessible locations potentially leading to protein unfolding.²⁷⁵ In the case of Met, it has been shown that solvent accessible residues are more readily oxidized than buried species,^{389,390} but oxidation of exposed residues does not appear to have marked effects on the conformation of most proteins,³⁹⁰ unless this residue is within an enzyme active site or in a binding pocket (e.g., in α_1 -proteinase inhibitor³⁹¹). Met sulfoxide is more polar than Met and can have marked effects on conformation.³⁹² Free energy calculations for the transfer of a residue from an α -helix inside a membrane to the aqueous phase indicate that Met and Phe side chains have the highest transfer free energy values,³⁹³ and the formation of oxidation products on these residues would therefore be expected to be a major driving force for changes in protein structure. Oxidation of only one of the eight Met residues (Met385) in α_1 -proteinase inhibitor results in the loss of the inhibition of elastase by this species. Similarly, oxidation of one of the vicinal (Met146 or Met147) residues in the C-terminal domain of

calmodulin has been shown to give rise to a large (30-fold) decrease in Ca^{2+} affinity.³⁹⁴

Not all oxidative events are, however, deleterious, and oxidation may result in a gain of function. Thus, oxidation of the Met-1 residue of ubiquitin to the sulfoxide results in a 50% increase in reactivity,³⁹⁵ and similar oxidation of Met residues in the native fifth component of human complement results in the conversion of this protein into its active form that binds component C6.^{396,397} Similarly, oxidation of a critical Cys residue is known to activate latent matrix metalloproteinases (the “cysteine switch” mechanism), with this process conserved across virtually the entire enzyme family.²⁷²

Oxidation of protein side chains has been proposed as a marker for protein degradation by cellular machinery.^{398,399} It has been proposed that oxidative modification results in enhanced turnover,^{400,401} although there is also evidence for decreased turnover with heavily modified material proteins.^{402–406} The cellular accumulation of heavily damaged, poorly degraded materials has been associated with lipofuscin accumulation and a wide range of human pathologies.^{407–411} In this respect, it is of interest to note that a number of protein oxidation products, particularly hydroperoxides, appear to be potent inhibitors of the proteolytic systems that are designed to remove damaged proteins. Thus, amino acid, peptide, and protein hydroperoxides have been shown to inhibit thiol-dependent lysosomal cathepsin enzymes⁴¹² and also the activity of the 26S proteasome.⁴¹³ These two systems constitute two of the major pathways by which cells remove modified/oxidized proteins and the impairment of their activity by the very molecules that they are supposed to remove may initiate a vicious cycle of protein damage and incomplete removal.^{412,413}

9 REPAIR OF PROTEIN DAMAGE

Although the prevention of protein oxidation is of immense industrial and biological importance, there are relatively little kinetic data available on the reaction of protein-derived radicals with antioxidants. This is probably due, at least in part, to the difficulties in generating known yields of specific radicals on proteins in the absence of other competing species. Some data have been obtained on the repair of amino acid radicals at neutral pH by Trolox C (a water-soluble vitamin E analog),⁴¹⁴

ascorbate,¹⁵¹ and GSH.⁴¹⁵ These data have been reviewed in Ref. 150.

With regard to repair of Trp-derived radicals, it has been shown that the Trp radical-cation reacts more rapidly than the neutral indolyl radical suggesting that repair can occur by electron transfer.⁴¹⁴ Repair of Trp-derived radicals on lysozyme by Trolox C has also been examined and shown to be a fast reaction ($k = 2\text{--}5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$).⁴¹⁴ The observation that repair of Trp radicals occurs with a rate constant similar to that for the free amino acid supports the hypothesis that at least some repair reactions are efficient and can occur over large distances. In contrast, vitamin E present in sodium dodecyl sulphate (SDS) micelles, although it can repair free Trp-derived radicals, cannot rapidly repair the same species when present in lysozyme.⁴¹⁶

Trolox C has also been shown to repair Tyr phenoxyl radicals in a number of proteins,^{202–206} and α -tocopherol has been demonstrated to repair Tyr phenoxyl radicals in lysozyme.⁴¹⁶ Other phenolic compounds (e.g., *n*-propyl gallate and sesamol) and vitamin C act in a similar manner.^{416,417} Trolox C, vitamins C and E, and thiols have been shown to react with protein and peptide peroxy and alkoxy radicals.^{148,200,201} These latter reactions are not, however, “repair” reactions, as the peptide remains as an oxidized species (either alcohols or hydroperoxides), although these reactions would be expected to inhibit chain reactions within a protein by exporting the radical into bulk solution.

Cys, *N*-Ac-Cys, and GSH can react with Tyr phenoxyl radicals on proteins, although this is reversible, and repair can only be effective if the thiyl radical is removed (e.g., via reaction with O₂ or thiol anions) before it reacts further.⁴¹⁸ Uric acid can also repair both Trp indolyl radicals and Tyr phenoxyl radicals in lysozyme when the protein is denatured (i.e., in the presence of SDS).⁴¹⁶ The modest difference between the rate constants for repair of the free Trp indolyl radical and the same species in lysozyme again suggests the occurrence of electron transfer processes. Bilirubin (and other molecules) that bind strongly to HSA or BSA appears to protect against damage, but it is unclear whether this is due to repair of radicals formed on the protein or by providing an alternative target for the attacking species.^{419,420}

The majority of protein damage does not appear to be repaired by cells, and the major fate of

oxidized proteins is catabolism. The only exceptions appear to be the repair of some oxidized Cys products and reduction of hydroperoxides and Met sulfoxide. Cystine and mixed disulfides can be readily reduced back to the corresponding thiols by multiple disulfide reductases/isomerases (e.g., glutaredoxins, thioredoxin, and protein disulfide isomerases). Similarly, the formation of nitrosocysteine (RSNO) and the sulfenic acid (RS-OH) can be readily reversed by biological reductants (both low-molecular-mass and enzymatic), particularly by thiol-dependent systems, although ascorbate can also play a role.^{421–427} Reduction of some Cys sulfenic acid residues also occurs via the action of sulfiredoxin enzymes, although this activity appears (currently) to be highly specialized and limited to reduction of the sulfenic acid forms of some peroxiredoxins by mitochondrial enzymes.^{428–430}

Amino acid, peptide, and protein hydroperoxides do not appear to be metabolized by many “traditional” antioxidant enzymes, with no reaction detected with many peroxidases, pseudoperoxidases, or catalase.^{431,432} Recent studies have, however, shown that these materials can be readily reduced by some members of the peroxiredoxin family with the corresponding formation of alcohols⁴³³ and possibly by glutathione peroxidase-4 (Davies, unpublished data). Reduction of these hydroperoxides can also occur with low-molecular-mass thiols (e.g., GSH) and ascorbate, although the rates of these reactions are highly variable and in some cases very slow.^{10,431,432,434} The formation of alcohols from these materials is not strictly a repair process; however, it is likely to limit any subsequent reactions of these hydroperoxides that might exacerbate oxidation.

Met sulfoxide is reduced by a family of Msr enzymes. These enzymes are highly specialized and stereospecific, with some of the Msr proteins specific for free Met sulfoxide and some handling only protein/peptide Met sulfoxide.^{435–442} These Msr proteins are predominantly intracellular and there appears to be little extracellular activity.⁴⁴³

A considerable number of studies have searched for evidence of other “repair” systems in cells and biological fluid. Many of these studies have been complicated by the occurrence of metabolic/catabolic processes that can also remove the damaged materials. As such, there is limited evidence for any major alternative routes of repair (as opposed to removal) of many of the

oxidation products listed in Tables 7 and 8, although this is an active field of research. Some evidence has been presented for the dechlorination of 3-chlorotyrosine,⁴⁴⁴ and the reduction of 3-nitrotyrosine to 3-aminotyrosine and/or the parent amino acid,^{445,446} but the biological significance of these reactions is yet to be fully established.

Electron Transfer in Peptides and Proteins

Bernd Giese, Sonja Eckhardt and Miriam Lauz

University of Fribourg, Fribourg, Switzerland

1 INTRODUCTION

Directed and controlled electron transfer (ET) reactions through proteins are vital for all living organisms for energy conversion and metabolic processes.¹ During photosynthesis, ET reactions play a crucial role, utilizing the energy of light for the production of O₂ and adenosine-5'-triphosphate (ATP), the energy storage molecule of cells.^{2,3} In addition, photosynthesis produces the so-called reducing equivalents, which allow the conversion of CO₂ into carbohydrates, the source of biomaterials on earth. Protein complexes, embedded in the chloroplast membrane, guide the ET processes, which are coupled with proton translocation through the membrane (Figure 1).⁴

In Catabolic processes of carbohydrates NADH (nicotinamide adenine dinucleotide) is synthesized, whose oxidation is the starting reaction of aerobic respiration. As in photosynthesis, the protein complexes of the respiratory chain through which ET occurs are also embedded into cell membranes, and again proton transfer takes place as a consequence of ET, driving the synthesis of ATP (Figure 2).⁵

Thus, long-distance ET through membrane-bound protein complexes occurs during energy conversion processes (photosynthesis and aerobic respiration). Long-distance ET is also known to take place in enzymatic reactions. An important example is the ribonucleotide reductase (RNR) that is essential for all higher organisms since this enzyme is needed to catalyze the conversion of ribonucleotides to deoxyribonucleotides, the building blocks of DNA

(see Section 7). In these enzymes, ET occurs over a distance of 35 Å from the generation site of a tyrosyl radical to the site where a cysteinyl radical triggers the conversion of ribonucleotide to deoxyribonucleotide (Figure 3).⁶

These examples show that ET through proteins is fundamental for all living organisms and that these reactions can occur over long distances.⁷ In most cases, these processes occur in multistep reactions. As an example, respiration needs 15 ET steps to take electrons from NADH, deposit them in O₂, and generate the electrochemical proton gradient that drives the ATP synthesis.⁸ Each single step can be described by the Marcus theory discussed below.

2 SINGLE-STEP ELECTRON TRANSFER

Marcus developed a theory for ET between an electron donor (D) and an electron acceptor (A) that are in close contact with each other.⁹ The physical parameters defining the ET rates are the driving force $-\Delta G^0$, and the reorganization energy λ , which is needed for the nuclear rearrangement during ET. An additional parameter, the electronic coupling matrix element H_{AB} , was introduced into the Marcus theory, which describes the probability that an electron tunnels through the potential barrier between D and A.^{10,11} These three parameters are summarized in the expression for ET rates given in (1) with the Planck constant (h), the temperature (T), and the Boltzmann constant (k_B):

Figure 1 Simplified depiction of the light-dependent reactions of the photosynthesis. Electron and proton flow due to the conversion of water into molecular oxygen and protons are shown, which lead to the production of NADPH and ATP. PQ, plastoquinone; PC, plastocyanine; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced form of NADP; ADP, adenosine-5'-diphosphate; ATP, adenosine-5'-triphosphate.

Figure 2 Simplified depiction of the aerobic respiration where the reducing potential of NADH and FADH₂ is converted to ATP through an electron transport chain with oxygen as terminal electron acceptor. ADP, adenosine-5'-diphosphate; ATP, adenosine-5'-triphosphate; CytC, cytochrome c; FAD, flavin adenine dinucleotide; FADH₂, reduced form of FAD; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced form of NADP; UBQ, ubiquinone.

Figure 3 Simplified depiction of the ribonucleotide reductase, which transforms ribonucleotide diphosphates (NDP) to deoxyribonucleotide diphosphates (dNDP) and therefore plays a fundamental role in DNA replication and repair. The active cysteine radical located in the α^2 -subunit (shown in green) is generated by an ET cascade over a distance of 35 Å by a diferric tyrosine radical cofactor.

$$k_{\text{ET}} = \frac{\sqrt{\frac{4\pi^3}{h^2 \lambda k_B T} H_{\text{AB}}^2}}{e^{\frac{(\Delta G^0 + \lambda)^2}{4 \lambda k_B T}}} \quad (1)$$

The reaction profile of a typical ET reaction, where the donor D is separated from the acceptor A by a bridge B is shown in Figure 4. The nuclear coordinates of the reactant and product states are described using classical harmonic oscillators. In this classical model, ET only occurs when the reactant and the product state have the same energy, since the principle of energy conservation has to be satisfied, and when they also have the same nuclear configuration according to the Franck–Condon principle. The only position fulfilling both conditions is the intersection point of the two parabolas.

The rate of ET between D and A also depends on their distance, and it is the electronic coupling matrix element H_{AB} that introduces the distance dependence on ET theory. The splitting at the intersection point is equal to $2H_{\text{AB}}$ (Figure 4). This strength of the electronic coupling between D and A, that is, the overlap between their orbitals, decays exponentially with the donor–acceptor separation as expressed in (2). The exponential factor β is a measure for the ability of the separating bridge (B) to mediate electronic coupling (superexchange), r represents the donor to acceptor distance, r_0 the close contact distance, and k_0 the ET rate for close

Figure 4 Intersecting parabolic potential energy surfaces are used to represent classical reactant and product harmonic oscillators for an ET reaction with the Gibbs free energy $\Delta G^0 < 0$. The parabolas at the left and right represent the reactant (D–B–A) and the product states, respectively. The figure shows the electronic coupling matrix element H_{AB} , which introduces the distance dependence on ET as well as the reorganization energy λ . This is the energy required to move along the product potential surface as the nuclear geometry is distorted from the average product configuration to the average reactant configuration.

contact:

$$k_{\text{ET}} \propto \frac{k_0}{e^{\beta(r-r_0)}} \quad (2)$$

In peptides, these separating bridges are the amino acids intervening D and A. The character of the bridge B exhibits a strong influence on the ET rate. In order to determine the strength of the electronic coupling, the orbitals of D, A, and B had to be mixed. A simple model was introduced by McConnell using n identical bridge units.¹² In this model, the coupling element H_{AB} is a function of the coupling between the redox sites (D and A) and the bridge B, the coupling between the bridge elements B_n as well as the energy gap between D and B (Figure 5).

Since peptides and proteins are built by up to 20 different amino acids, the McConnell model is too simple to explain the details of ET through these biomolecules. In order to gain a deeper understanding, Gray and Winkler¹³ measured the ET rates of several proteins. Using metalloproteins

Figure 5 Energy diagram for superexchange ET between donor D and acceptor A across a bridge of n identical units B_n . The bridge orbitals are involved in the electronic coupling between the donor and acceptor leading to a lower potential barrier and therefore facilitate the ET. The rate depends on the coupling between the redox sites and the bridge, the coupling between the bridge elements, and the energy gap between the orbital donating the electron and the reduced bridge states δE .

with copper (azurin) or iron (cytochrome) cofactors, they attached ruthenium complexes to specific histidine residues at defined distances from the cofactors. Figure 6 shows the results of an azurin series.¹⁴ The measured ET rates fitted well with the exponential distance dependence of (2). From the

Figure 6 Distance dependence of the ET rate (k_{ET}) in modified azurins (arsenate reductase) with Ru complexes attached to six different positions on the surface of the metalloprotein. The ET rates from the metal cofactor (copper) to the oxidized ruthenium complex were measured by absorption spectroscopy using the flash-quench technique.

slope, a β -value of 1.1 Å^{-1} resulted for the peptides adopting a β -sheet.

For several other peptides, ET rate data could not be explained by the distances between D and A alone, and in some proteins, ET rates for similar D to A distances differed by several orders of magnitude. Gray and Winkler therefore concluded that a structural analysis of the peptide matrix is necessary in order to understand ET processes. Beratan *et al.*¹⁵ developed a model that links protein structures to their ET properties. According to their model, the electronic coupling depends on the specific bridging connections between D and A (covalent bonds, H-bridges, and Coulomb bonds). These interactions make different pathways for ET through peptides possible. For each pathway, the coupling strength can be calculated as a function of all possible bonding contacts that correspond to β -values of at least 1.0 Å^{-1} and nonbonding contacts of about 2.0 Å^{-1} . If the protein is very flexible, fast conformational averaging might occur and the matrix exhibits an average β -value.

A different approach was suggested by Dutton in his “uniform barrier” model, which assumes a uniform behavior of all bridging units.¹⁶ He derived a β -value of 1.4 Å^{-1} from studies on the bacterial reaction center as well as on synthetic peptides. In a refined version, the atomic packing is also taken into account. Anyhow, in the case of ET reactions in peptides and proteins, β -values larger than 1.0 Å^{-1} lead to such a strong distance dependency that single-step ET over more than 14 Å (Dutton)¹⁶ or 20 Å (Gray and Winkler)¹³ cannot occur under biological conditions. Nevertheless, long-distance ET in proteins exists, and it is today a well-accepted theory that, in analogy to DNA, multistep reactions (hopping) can make long-distance ET possible in peptides and proteins as well.

3 HOPPING

3.1 General Aspects

The hopping model of ET through biopolymers was first developed for DNA in order to explain the observation that ET in double-stranded DNA can occur over very long distances ($>100 \text{ Å}$). According to this model, a positive charge, induced into guanine (G), can migrate through double-stranded

Figure 7 ET between guanine (G) bases separated by n A·T base pairs. For short distances ($n = 1-3$) superexchange between the guanine bases was observed, a process referred to as G-hopping. However, for long distances ($n > 4$), adenines were acting as additional stepping stones, a mechanism known as A-hopping. The DNA double strands with $n = 2$ and 5 are shown as example for each case and the nucleotides shown in red indicate the stepping stones of the ET process.

DNA in a multistep reaction using the other Gs as stepping stones at which the charge has a distinct lifetime (Figure 7).¹⁷ As a consequence, one long ET reaction is divided into several short and therefore much faster ET steps. The stepping stones act as electron donor in the first step and as electron acceptor in the subsequent reaction. Furthermore, if the distance between the Gs is so long that the ET rate becomes slow, the intervening adenines (A) can also become stepping stones (Figure 7), as the endothermic oxidation of the neighboring A is faster than the thermoneutral oxidation of a distant G.¹⁸

Each single reaction step follows (1), but the overall process cannot be described by (2). The ET rate for the hopping reaction is much less distance dependent than the superexchange process. If the hopping steps k_n are of the same rate, and if all steps (n = number of steps) are reversible, the overall ET rate k_{ET} decreases with n^2 , as shown in (3).^{17,19,20} In many cases, one of the hopping steps becomes the rate-determining step:

$$k_{ET} \propto \frac{k_n}{n^2} \quad (3)$$

If hopping explains long-distance ET through peptides and proteins, the question remains, which of the 20 natural amino acids in peptides can play a similar role as the nucleic acids in DNA and what are the conditions for a mechanistic change from a single-step reaction as in **1** (Figure 8a) to a hopping process as in **2** (Figure 8b).²¹ In order to find an

Figure 8 Possible ET pathways through peptides **1** and **2**. In **1**, ET occurs via a single-step reaction if there is no redox-active side chain at position X between the donor (D) and acceptor (A). In contrast to this, ET may occur via a two-step hopping mechanism if there is an amino acid with a redox-active side chain at position X between D and A (peptide **2**).

answer, we have carried out laser experiments with a model peptide. The goal was to detect all reactive intermediates and to determine the rates of the ET reaction steps.

3.2 Peptide Assay

As model peptide, nonapeptide **3** turned out to be a suitable assay for the study of ET processes through peptides (Figure 9).²¹ It consists of tyrosine, which functions as an electron donor (D), a dialkoxyphenylalanine, which can be used to generate the electron acceptor (A), and a third amino acid with side chain

Figure 9 Peptide assay **3** for the investigation of intramolecular ET, with an electron donor (Tyr) at the N-terminal end, a dialkoxyphenylalanine that can be transformed into an electron acceptor at the C-terminal end, and a side chain X that might act as a relay station.

Figure 10 Generation of the radical cation (**6**), which acts as electron acceptor (A) in our model peptides, by laser flash photolysis of **4**.

X that might act as stepping stone for a hopping process.²² The latter is often referred to as relay amino acid or relay station. These three amino acids are separated from each other by rigid bridges consisting of three prolines.

A laser flash was used to generate a radical cation in the side chain of the dialkoxyphenylalanine, which then functions as an electron acceptor (A) during the ET reaction. The formation of this radical cation is shown in Figure 10. Photoexcitation of **4** by an excimer laser at 308 nm initiates a Norrish type I reaction that after β -elimination leads to intermediate **5**, which yields the electron acceptor **6** (A).²¹

Model peptide **3** fulfills all prerequisites for a successful investigation of ET through peptides. The electron donor tyrosine provides a sufficient driving force because deprotonation of the hydroxyl group leads to a nonreversible trapping of the charge. The overall ET process is exothermic by 0.37 V since the redox potentials of tyrosine, used as electron donor, and dialkoxyphenylalanine, whose radical cation is the electron acceptor, are 0.93 and 1.30 V, respectively. The electron acceptor can be generated selectively at a specific position in the peptide, and the UV/Vis spectra of the electron acceptor ($\lambda_{\text{max}} = 450$ nm) and the tyrosyl radical ($\lambda_{\text{max}} = 410$ nm) differ from each other so that they can be detected simultaneously. In order to minimize the influence of the peptide conformation on the ET rate, rigid peptide bridges were chosen. With two triproline spacers, a separation of donor (D) and acceptor (A) of about 20 Å was achieved due to their PPII (polyprolineII) helical structure.^{22–24} These proline sequences mediate ET but proline itself does not function as relay amino acid since its side chain

cannot be easily oxidized. Our peptide assay provides the opportunity to place different amino acids between donor and acceptor as indicated in Figure 9 (variation of side chain X) in order to answer the question which amino acids can act as relay stations. The functionality of this model system was then tested with trimethoxyphenylalanine as possible relay amino acid.²¹ Its redox potential of 1.30 V is low enough to act as relay station, and its absorption maximum ($\lambda_{\text{max}} = 550$ nm) allows the simultaneous detection of all three different reactive intermediates that are generated during the ET reaction, as shown in Figure 11. The radical cation of the electron acceptor in **7** yields the radical cation of the trimethoxyphenylalanine **8** in the first ET step. A second ET step leads to the formation of tyrosyl radical **9** (Figure 11).

The peptide assay **3** (X = trimethoxyphenylalanine) was irradiated by a laser flash, and the transient absorption spectra were recorded after a defined time delay. The spectrum obtained 40 ns after the laser flash (Figure 12, black curve) is a superposition of the absorption spectra of all three reactive intermediates. It is therefore possible to observe all three generated intermediates at the same time (Figure 12, colored curves). Taking into account their different extinction coefficients, it is furthermore possible to estimate their relative concentrations.

This demonstrates not only the quality of this assay for the investigation of ET processes in peptides, it furthermore provides a direct proof of the action of trimethoxyphenylalanine as relay station in a two-step hopping process, since 10% of its radical cation were detected 40 ns after the laser

Figure 11 After generating the radical cation **7** by laser flash photolysis (LFP), ET through our model peptide takes place in a two-step hopping mechanism with trimethoxyphenylalanine as relay station (**7** → **8**) and tyrosine as electron donor (**8** → **9**). The deprotonation of tyrosine makes the overall ET reaction irreversible.

flash. Measurements between 40 and 500 ns lead to rate constants for the two hopping steps of $3.3 \times 10^6 \text{ s}^{-1}$ (first step) and $3.0 \times 10^7 \text{ s}^{-1}$ (second step).²⁵ This 10-fold rate difference is another proof for the applicability of this peptide assay, as the first step is thermoneutral but the second step is exothermic by 0.37 V. According to the Marcus theory, this change in the reaction enthalpy should lead to a rate increase (see Section 2).

Comparison with a peptide where the relay amino acid trimethoxyphenylalanine was exchanged by alanine ($X = \text{CH}_3$) demonstrated that in assay **3**, the two-step hopping reaction is at least one order of magnitude faster than single-step ET.²¹ The oxidation potential of alanine is so high that it

cannot act as relay station, and ET occurs in a superexchange one-step reaction over a long distance. By variation of the side chain X in peptide assay **3**, the behavior of other amino acids in ET processes could be studied, as presented below.

4 TRYPTOPHAN, TYROSINE, AND HISTIDINE AS RELAY AMINO ACID

So far, mainly the aromatic amino acids tyrosine (Tyr) and tryptophan (Trp) have been discussed to act as relay amino acids since the oxidation potentials of their side chains (0.93 V for Tyr and

Figure 12 Transient absorption spectrum of peptide assay **3** 40 ns after the laser flash (black line). The absorption spectra of the transient intermediates are shown in blue **9** (tyrosyl radical, $\lambda_{\text{max}} = 410$ nm), green **8** (2,4,6-trimethoxyphenylalanine radical, $\lambda_{\text{max}} = 550$ nm), and red **7** (dialkoxyphenylalanine radical, $\lambda_{\text{max}} = 450$ nm). They are fitted to estimate the amounts of transients generated by laser flash photolysis of **3**.

1.03 V for Trp at pH 7)²⁶ are small enough to become easily involved in naturally occurring redox processes (see **Oxidative Damage to Proteins**).^{6,27,28} The results of ET experiments with several proteins, for instance, photolyase, RNR, or azurin, can best be understood if tryptophan acts as a relay amino acid in the hopping process. Brettel and Byrdin²⁸ have suggested that the activation of the DNA repair enzyme photolyase uses three tryptophan molecules in an ET hopping sequence. Stubbe *et al.*⁶ have studied tryptophan as relay amino acid in the ET process that generates the cysteinyl radical in RNR, which is a vital enzyme for the DNA synthesis (see Section 7). Gray and Winkler²⁷ have explained the fast oxidation of Cu(I) during ET through azurin by electron hopping, assuming tryptophan as a relay amino acid. These examples demonstrate that tryptophan is an appropriate relay amino acid. Experiments with our peptide assay **10** where tryptophan is centered between donor and acceptor show that tryptophan is an efficient electron donor but the next step, which is the electron abstraction from tyrosine, is rather slow.^{29,30} The reason is that under our reaction conditions (pH 7 buffer, $\text{CH}_3\text{CN}/\text{H}_2\text{O} = 3 : 1$ as solvent) the oxidized tryptophan becomes deprotonated, which reduces the oxidation potential of the reactive intermediate (stepping stone). The next ET step has to occur in a proton-coupled electron transfer (PCET)

reaction (Figure 13), a term introduced by Huynh and Meyer in 1981.³¹

In peptide **10**, tryptophan is a poor relay amino acid for the hopping process **10** → **11** → **12** because of the proton transfer from the tryptophan radical cation to the solvent. Nevertheless, tryptophan might act as an effective relay station for ET processes if the proton remains bound to the peptide so that it can be transferred back to the tryptophanyl radical during the next hopping step. The two-step ET process is thus coupled with a proton shuttle. In RNR, whose ET pathway has been discussed in more detail in Section 7, the amino acid Asp²³⁷ being in close contact to Trp⁴⁸ makes this proton shuttle possible (Figure 14).⁶ These two examples already demonstrate the importance of PCET processes, recently reviewed in a special *Chemical Reviews* issue.³²

In the DNA photolyase, three tryptophans are believed to facilitate long-range ET. Before catalysis the enzyme needs to reduce a flavin cofactor ($\text{FADH}^\bullet$) to its active form (FADH^-). This process occurs by photoactivation of $\text{FADH}^\bullet$ and subsequent ET over 15 Å with three highly conserved tryptophan residues (Trp³⁸², Trp³⁵⁹, and Trp³⁰⁶) on the pathway. The different redox potentials of the tryptophanyl radical and its radical cation are important for the efficiency of the photoactivation of this enzyme. At the end of the pathway, a deprotonation

Figure 13 PCET for tryptophan as stepping stone in peptide **10**. After the first ET step, the deprotonation of the oxidized tryptophan reduces its oxidation potential and therefore slows down the second ET step (**11** → **12**), making tryptophan a rather weak relay amino acid in our peptide assay.

step prevents back ET, allowing the catalytic cycle to take place (Figure 15).²⁸ This pathway was first postulated by Aubert *et al.*,³³ but the ET could not be monitored by transient absorption since the ET between identical residues does not change the net absorption. However, polarized light was used in order to construct transient anisotropy spectra due to the different orientation of the tryptophan residues. These studies demonstrate that the ET occurs quickly so that the only oxidized tryptophan residue observed is the terminal one (Trp³⁰⁶). For a mutant in which the terminal Trp was substituted by the redox-inactive phenylalanine, the Trp³⁵⁹ radical was observed, giving strong evidence for the proposed ET pathway.²⁸

Figure 14 Tryptophan can only act as efficient stepping stone in ET processes if after deprotonation the proton stays in the proximity of the tryptophan residue. In ribonucleotide reductase, the ET is coupled with a proton shuttle between tryptophan (Trp⁴⁸) and aspartic acid (Asp²³⁷) allowing ET with tryptophan as a stepping stone.

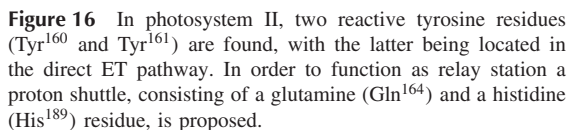

Figure 15 In DNA photolyase, a photoactivated flavine (FADH•*) has to be converted into its active form (FADH⁻). This is achieved by ET over three highly conserved tryptophan residues (Trp³⁸², Trp³⁵⁹, and Trp³⁰⁶) followed by a deprotonation of the last tryptophan to make the overall ET irreversible.

Similar to tryptophan, tyrosine can also act as a relay amino acid in ET reactions. Prominent examples are found in photosystem II (PSII) and in RNR. Since the tyrosine radical cation is a strong acid (pK_a approx. -2), deprotonation occurs during ET, which decreases the oxidation potential of the intermediate and slows down the subsequent hopping step. As discussed above for tryptophan,

The last remaining redox-active aromatic amino acid (histidine) is by its redox potential of 1.17 V,³⁷ also a conceivable relay amino acid. Unfortunately, the UV/Vis spectrum of histidine is very weak, and due to the deprotonation of the histidiny radical cation, the subsequent hopping step is again slowed down. Nevertheless, in our model assay **3** (X = imidazole), the electron donor tyrosine was oxidized with histidine acting as a relay amino acid, but the efficiency of this ET process was rather weak.²⁹ This is in accordance with the low ET rate of intramolecular tyrosine oxidation by the histidiny radical (Figure 17), as observed by Morozova and Yurkovskaya³⁸ for the dipeptides (Tyr-His and His-Tyr) by time-resolved chemically induced dynamic nuclear polarization.

Sulfur is essential for all organisms from microbes to the human being, where sulfur-containing amino acids are known to be part of biological ET processes.³⁹ The cysteinyl radical, for example, is the reactive species formed by an ET cascade as the initial step in all three classes of RNRs (see Section 7).^{6,40} Sulfur is also an essential part of the human defense mechanism against oxidative damage caused by reactive oxygen species (ROS), which are considered to be one of the reasons for aging⁴¹ and neurological disorders such as Alzheimer's or Parkinson's disease (see **Radical-Based Damage of Sulfur-Containing Amino Acid Residues**).^{42,43} Experiments with our model peptide **3** (Figure 9), where we situated the sulfur-containing amino acids between the electron donor and acceptor, showed that both cysteine and methionine can function as real stepping stones in ET reactions.

Figure 18 Cysteine was expected to be a poor relay station due to its deprotonation during oxidation, which should slow down the subsequent hopping step. However, water-mediated PCET between the cysteinyl radical and tyrosine enables sufficient ET in peptides.

Cysteine, whose oxidation potential of 0.92 V should be suitable for our system, was nevertheless expected to be a poor relay station due to its deprotonation during oxidation. However, our experiments showed a surprisingly efficient ET transfer with 15% of tyrosyl radical having been formed already after 40 ns. We have explained this by a water-mediated PCET as illustrated in Figure 18.^{29,30} In the first step, an electron is transferred from cysteine to the dimethoxyphenylalanine radical cation (**13** → **14**) followed by deprotonation yielding the thiyl radical. In a subsequent reaction, this thiyl radical is reduced by tyrosine in a water-mediated PCET reaction. This mechanism is supported by a deuterium isotope effect of about 2. In contrast to tryptophan or histidine, where the water-mediated PCET was not very effective in our assay (see Section 4), water could enable proton shuttling with cysteine as a relay amino acid because cysteine is more hydrophilic than the aromatic side chains, and there are more reaction pathways for a successful proton transfer than that in the heterocyclic amino acids.

Water molecules as mediators are also discussed in natural systems. Two prominent examples are

Figure 19 Water molecules play an important role in ET processes in natural systems. In ribonucleotide reductase, an electron is transferred from tyrosine (Tyr¹²²) to a diferric cofactor. Simultaneously, a water-mediated proton transfer has to take place as well.

RNR and cytochrome *P450*. In RNR, the formation of the tyrosyl radical, which induces the ET pathway (see Section 7), is a process during which an electron and a proton have to be transferred from tyrosine to a diferric cofactor. Quantum chemical calculations suggest a bridging water molecule between the diiron complex and tyrosine since the computed barrier without the water molecule is far too high.⁴⁴ A possible transition state proposed by Siegbahn is shown in Figure 19, which allows both proton and electron transfer. This leads to a computed barrier of 10 kcal mol⁻¹ for the tyrosyl radical formation, proposing a rapid transfer in the order of microseconds.⁴⁵

The biosynthesis of staurosporine, a natural alkaloid with a strong inhibitory activity on protein kinase or DNA topoisomerase I, involves the aryl–aryl coupling of two chromopyrrolic acids (CPAs → K252c), which is catalyzed by the cytochrome *P450* enzyme StaP (Figure 20a). Nagano and coworkers suggested a water-mediated PCET process.^{46,47} The proton transfer during oxidation of CPA shown in Figure 20b is made possible via the hydrogen-bonding network involving two molecules of water and a histidine residue (His²⁵⁰). Also, the aromatization steps following the C–C coupling are mediated by these two water molecules. In addition, the study of a mutant in which the histidine residue in the hydrogen bonding network is substituted by a phenylalanine reveals that the water diad seems to be the minimal requisite for enzymatic activity. The water molecules can therefore be regarded as biological catalysts.

Even more surprising than the proof of cysteine being a relay amino acid are our results^{29,30} indicating that methionine can also function as a stepping stone in ET processes, although the high redox

Figure 20 PCET during the biosynthesis of staurosporine. (a) The biosynthesis of staurosporine includes an aryl–aryl coupling reaction of two chromopyrrolic acids (CPAs) yielding the indolocarbazole scaffold (K252c). (b) The activation of CPA by PCET involves two molecules of water.

Figure 21 Neighboring amide participation lowers the redox potential of thioethers due to the formation of a stabilized radical. (a) The redox potential of the norbornene derivatives **15** and **16** differs by 0.33 V since for the endo derivative **15**, the formation of a captodative stabilized radical cation **17** is possible. For the exo compound **16**, the resulting radical cation **18** cannot be stabilized by a neighboring amide function, resulting in a higher redox potential. (b) Neighbor group participation **20** is also possible in our peptide assay, as shown for the fragment **19**, reducing the redox potential of methionine which makes it a stepping stone in ET reactions.

potential of thioethers (e.g., dimethylsulfide: 1.66 V vs normal hydrogen electrode)⁴⁸ should make the first ET step endergonic. This result can be explained by a neighboring group effect of the adjacent amide function that lowers the redox potential of methionine so that it can act as a stepping stone in our assay. The influence of neighboring amides on the redox potential has, for example, been demonstrated by the norbornene systems **15** and **16** (Figure 21a), in which the amide group at endo position (**15**) reduces the redox potential by 0.33 V compared to **16**, where the amide function is situated at the exo position. The effect is explained by the formation of a captodative stabilized radical cation (**17**), which cannot be generated during the oxidation of the exo compound (**16** → **18**) (see **Radical-Based Damage of Sulfur-Containing Amino Acid Residues**).^{49,50} The formation of a similar stabilized radical cation (**20**) should also be possible in the case of our model peptide (**19**) (Figure 21b). An analog situation is also discussed for other peptides making methionine a target of oxidative stress,⁵¹ since it is one of the most easily oxidized residues by ROS (reactive oxygen species).⁵² For methionine, the damage due to ROS is reversible as the methionine sulfoxide formed can be enzymatically reversed to methionine by methionine sulfoxide reductase.⁵³ Therefore, methionine residues have been considered as protecting system against ROS.⁵⁴ In contrast to the oxidation to methionine sulfoxide, the one-electron oxidation forming the methionine radical cation is discussed as an important parameter in the pathogenesis of Alzheimer's disease. It was found that Met³⁵ in the β -amyloid peptide is critical for generating oxidative stress by initiating metal ion-dependent production of ROS.^{51,55} Molecular modeling results predict a neighbor group participation of isoleucine (Ile³¹) for this Met³⁵ residue.⁵⁶ Recently, a sulfimide bond, the nitrogen analog of a sulfoxide, was identified in collagen IV.⁵⁷ This bond formation can be explained by an oxidative cross-linking between methionine and an adjoining hydroxylysine.

Besides the two naturally occurring sulfur-containing amino acids, it was also possible to study ET in our peptide assay **3** with a cystine model containing the characteristic disulfide bridge (X = CH₂SSCH₃). The cystine model turned out to be an effective stepping stone in ET reactions as well, as it was expected from the redox potentials of cystine (1.25 V).⁵⁸

These results show that in addition to the redox-active aromatic amino acids tryptophan, tyrosine, and histidine, sulfur-containing aliphatic amino acids should also be taken into account as possible relay stations in ET reactions when ET in proteins/enzymes is discussed.

6 INFLUENCES OF THE PEPTIDE BACKBONE

6.1 Dipole Moment

Isied and coworkers have recently published theoretical studies on the influence of the peptide conformation on ET rates,^{59,60} predicting that the peptide conformation strongly influences the electronic coupling matrix element H_{AB} of (1). They calculated H_{AB} -values for 576 different peptide conformations and used these values in order to create a Ramachandran-like plot. It could be shown that the largest H_{AB} -values are found in H-bonded helical peptide conformations, including the α -, γ -, and 3_{10} -helices. In addition, the distances between donor and acceptor turned out not to be the only critical parameter influencing ET rates, but specific torsional peptide angles play a major role as well. With their calculations, the authors concluded that rate differences as high as eight orders of magnitude can be achieved for peptides with the same primary but different secondary structures. Along with different conformations comes a change in the overall dipole moment. In their theoretical studies, Isied and coworkers have also described an influence of the dipole moment on ET rates. Therefore, a rate difference between opposing directions of the ET should be observed if the peptide has an overall dipole moment along its backbone. Depending on the solvent, they predicted ratios of ET rates in opposing directions of approximately 8.5 for the α -helix and 1.1 for a PPII-helix.

First experiments investigating the influence of dipole moments on ET rates were carried out with α -helical peptides by Fox *et al.*^{61,62} The α -helix is a right-handed helix stabilized by hydrogen bonds between the amino acids i and $i + 4$.⁶³ With all the carbonyl groups pointing in the direction of the C-terminus, the α -helix shows a large overall dipole moment with its negative end at the C-terminus and its positive end at the

Figure 22 Peptides **21** and **22** used by Fox *et al.* show the influence of the dipole moment on ET rates. (a) If the peptides exist in a α -helical conformation, there is a dependence of the ET rates on the ET direction caused by the overall dipole moment. (b) If the α -helix is denaturized and the peptide adopts a random coil conformation, no difference in the ET rates in dependence of the ET direction was observed.

N-terminus, each amino acid contributing approximately 5.0 D.⁵⁹ Fox *et al.* synthesized α -helical peptides consisting of 14 amino acids with Ala-Aib (Aib = α -aminoisobutyric acid) repeating units and an electron acceptor/electron donor pair within a distance of 10 Å (Figure 22). In laser experiments, they studied ET in both directions along the peptide backbone and reported that depending on the solvent, the rates in the direction C $\rightarrow$ N (**21**) were 5–27 times faster than those in the opposite direction (**22**). In order to investigate whether this effect is really due to the dipole moment, the helix conformations of these peptides were denaturized. With the resulting random coils, the ET measurements

were repeated and were found to be identical in both directions along the denaturized peptide backbone. These results show the major influence a conformation and its overall dipole moment can have on ET rates.

Similar results have also been reported by several groups for α -helical peptides, which are self-assembled on gold surfaces. For instance, Sek *et al.*⁶⁴ used polyalanine to form self-assembled monolayers (SAMs) on gold surfaces and found that ET from the C- to the N-terminus was faster by a factor of 1.4 than that in the opposite direction. Kimura and coworkers synthesized α -helices consisting of Ala-Aib repeating units to form SAMs on gold surfaces, with which they could also show that the dipole moment has a major influence on the ET.^{65–67}

Experiments with 3_{10} -helical peptides were carried out by Gatto *et al.*⁶⁸ These helices are right-handed as well, but the alignment of the carbonyl groups is not as perfect as that of α -helices, resulting in a lower overall dipole moment (4.6 D per residue). In this study, oligopeptides with α -disubstituted amino acids, pyrene as electron donor, and azulene as electron acceptor were synthesized and the ET rates in opposite directions through the peptides were measured, resulting in a ratio of approximately 1.7. This factor is significantly lower than the one found by Fox *et al.* for α -helices, but although the reaction conditions are not directly comparable, the authors suggest that this is due to the lower overall dipole moment of the 3_{10} -helix. Similar effects were observed with α - and 3_{10} -helices, self-assembled on gold surfaces.⁶⁹

We investigated the influence of the dipole moment on ET reactions through PPII-helical peptides.^{25,29} In a PPII-helix, the amide bonds are in trans-conformation, resulting in a left-handed helix, which is not stabilized by hydrogen bonds and which has a weak dipole moment with its negative end at the N-terminus and the positive end at the C-terminus, with each amino acid contributing approximately 1.5 D.^{23,59} In order to investigate the influence of the dipole moment on ET through PPII-helices, we used our model peptide **7** and compared its ET rates with those of assay **23**, where ET occurs in the opposite direction (Figure 23). It was observed that ET from N- to C-terminus is 2.5 times faster than that in the opposite direction, indicating that the dipole moments in PPII and α -helices are opposite to each other.²⁵

Figure 23 Influence of the dipole moment in PPII-helical peptides. (a) Our model peptide was used to investigate the influence of the dipole moment on intramolecular ET, by comparing the ET rates in opposing directions. (b) In a PPII-helix, the overall dipole moment has its negative end at the N-terminus and its positive end at the C-terminus. We measured a difference in ET rates of a factor of about 2.5 for the ET reactions in opposing directions.

6.2 Charges

Because dipole moments influence ET rates in peptides, charges (e.g., ammonium or carboxylate ions) should play an even larger role. However, to our knowledge, no other studies than ours have been reported so far.²⁵ The same type of model peptides (**7a,b** and **23a,b**) that were already employed to determine the influence of the dipole moment (see Section 6.1) are now used to investigate the charge effect on the ET rates, with the only difference that the N-termini are protonated instead of acetylated. The rates of the charged peptides were then compared with those of the uncharged peptides (Figure 24).

From experiments with peptide **7** (ET from N $\rightarrow$ C, Figure 24a) it could be concluded that the charge

only influenced the neighboring ET rate, which was slowed down by a factor of four. The ET reaction between the relay and the C-terminal amino acid, which is the distal hopping step, was left rather unaffected (within the experimental error). For peptide **23** (ET in the direction C $\rightarrow$ N, Figure 24b), a rate acceleration by approximately one order of magnitude was found. This influence of the ammonium ion on the adjacent hopping step can be explained by a change in the Coulomb repulsion. In the neutral peptide **23a**, the Coulomb energy remains unchanged as the charge is shifted. Contrary to this, in peptide **23b** (Figure 24b), two positive charges are in close proximity before the ET reaction and far from each other after the hopping step. If one assumes the distance between the charges before the ET step to be 3 Å (determined by calculations), a Coulomb repulsion of about 3.0 kcal mol⁻¹ can be calculated, making the ET in the charged peptide more exergonic than the analogous ET step in the neutral peptide.²⁵ By applying the Marcus theory for the case that $|\Delta G^0/\lambda|$ is small, which is the case in our system since the redox potentials of the trimethoxyphenylalanine and the dialkoxyphenyl side chain are nearly identical, a change in the Coulomb energy of approximately 3.0 kcal mol⁻¹ corresponds to an activation free energy difference of about 1.5 kcal mol⁻¹. Employing the Gibbs equation, one can calculate that this difference in activation free energy leads to a rate difference by a factor of about 10 (at 25 °C), which is in excellent agreement with our measurement.²⁵ These results clearly show that charges significantly affect ET rates in peptides. With the experiments described above, we only investigated the influence of a positive charge. However, preliminary experiments with negatively charged peptides (carboxylate instead of methyl ester) as well as zwitterionic species showed that negative charges also affect ET rates. A possible future investigation in this field is to determine the influence of charged side chains since there are five natural amino acids with acidic/basic side chains (lysine, arginine, histidine, aspartic acid, and glutamic acid), where charges could be easily introduced by controlling the pH. Another interesting topic would be to find out whether it is possible to switch the direction of ET reactions. This question might be addressed with our model system by installing two

Figure 24 Influence of charges on intramolecular ET rates through our model peptides. (a) Comparison of the ET rates for a protected, uncharged (**7a**) and an unprotected, charged (**7b**) peptide with ET proceeding from the N- to the C-terminus. (b) Comparison of the ET rates for a protected, uncharged (**23a**) and an unprotected, charged (**23b**) peptide with ET proceeding from the C- to the N-terminus. In this case, only the rate constants k_1 for the first hopping step could be measured. $\text{TFA}^- = \text{CF}_3\text{COO}^-$.

aromatic amino acids with different redox potentials on both termini and the injection system centered in the middle of the peptide. An example for this approach is shown in Figure 25. By having tyrosine at the N-terminus, trimethoxyphenylalanine at the C-terminus and the radical cation between one expects tyrosine to be the electron donor in the neutral peptide **24a** due to its lower redox potential compared to trimethoxyphenylalanine. By introducing a positive charge at the N-terminus and/or a negative charge at the C-terminus (**24b**), it would be interesting to see whether this leads to trimethoxyphenylalanine becoming the electron donor, thereby inverting the ET direction.

Experiments of this kind might give an insight into whether nature uses basic and/or acidic amino acids to control ET rates or even ET directions in proteins.

6.3 Amides as Possible Stepping Stones

Recently, it has been suggested that amide bonds might act as stepping stones in long-range ET through peptides. Already in 1996, it was reported that excess ET from a nonbonding carboxylate orbital to a π^* orbital of the amide group was observed for dipeptides and that this transition might play an important role in ET through peptide backbones.⁷⁰ In 2004, Isied *et al.* have published work on Ru(II)/Ru(III) containing peptide complexes (**25**), where they varied the number of prolines (n) between 0 and 9, therefore enlarging the distance between donor and acceptor from 8.7 to 32 Å (Figure 26).⁷¹ With $n = 0$ –4, they could observe a strong distance dependence, which is consistent with a superexchange mechanism,

Figure 25 Switching the ET direction in peptides with a radical cation surrounded by different redox-active amino acids. (a) In the neutral peptide **24a**, the ET should proceed in the direction N $\rightarrow$ C due to the different redox potentials of tyrosine and trimethoxyphenylalanine. (b) In the zwitterionic species **24b**, a change in the ET direction should be observed due to the effects of charges on ET rates.

but for longer peptide bridges ($n = 5-9$), only a weak distance dependence was found that could be explained by a switch from the superexchange to the hopping mechanism.

For the measurements of fast ET rates, photochemical, and for the determination of slow ET rates, radiolytical methods were used. Since the reaction enthalpies ΔG^0 and the reorganization energies λ are different under these two different reaction conditions, the observed ET rates had to be corrected according to the Marcus theory.⁷¹ It should be noted that in these experiments, excess ET occurs. Under these reductive conditions, the amide groups can act as stepping stones if the distance between electron donor and acceptor is so long that the superexchange becomes very slow.

Kimura and coworkers used peptides with an Ala-Aib repeating unit for their electrochemical investigations of ET through α -helices.^{72,73} They synthesized 8-, 16-, 32-, 48-, and 64-mer peptides, ranging from 30 to 110 Å in length, self-assembled them on gold surfaces, and studied ET through the helices. Since they found only a weak distance dependence of ET rates with elongation of the peptide chain, they proposed a hopping mechanism, which uses the amide groups of the peptide

backbone as stepping stones. They suggested that the electron is first transferred from the N-terminal amide to the gold surface, generating the amide radical cation. The electron hole then hops among the amide groups to the C-terminal end, where the amide radical cation is reduced by the electron donor ferrocene (Figure 27). The oxidation potential of the amide bonds was measured to be 0.93 V versus Ag/AgCl in these α -helical peptides, whereas the oxidation potential for isolated peptide bonds⁷⁴ is known to be 1.95–2.10 V versus Ag/AgCl. This unexpected low value was explained either by stabilization of the amide radical cation by neighboring amide groups, by delocalization over a few amide groups, or by three-electron bond formation.

The suggestion that amide groups, when situated in an α -helix, can act as relay stations for ET under oxidative conditions is also supported by calculations carried out by Cukier and coworkers, who published *ab initio* calculations showing that the C-terminus of an α -helix could act as a relay element.⁷⁵ They used α -helical polyglycines and calculated vertical ionization potentials (IP_vs) in dependence of the helix length, and compared their findings with the IPs of known relay amino acids.

Figure 26 Isied *et al.* found a change in the mechanism of ET processes through peptides of different lengths (25). The fast rates were determined by photochemical (circles) and the slow rates by radiolytical methods (squares). The observed rates were corrected according to the Marcus theory. For short distances (r) superexchange ET and for long distances hopping using the amide bonds as stepping stones occur. Bpy = 4-carboxyl-4'-methyl-2,2'-bipyridine.

For Gly_n with $n = 4-15$, they found IP_v values ranging from 8.13 to 6.74 eV, and the inspection of spin densities showed that the electron hole is predominantly located in the region of the

C-terminus. The IP of tryptophan (a known relay amino acid, see Section 4), is 7.49 eV, implying that on a certain helix length ($n > 9$), the C-terminal amide could be a more preferential stepping stone than tryptophan. In order to further investigate this hypothesis, Cukier and coworkers replaced the second N-terminal glycine by tryptophan and calculated the spin densities in dependence of the helix length. For shorter helices ($n \leq 5$), the hole preferred the tryptophan, whereas for longer helices ($n > 8$), the hole was always found at the C-terminal end. In the case of medium-length sequences ($n = 6-8$), no clear preference could be observed. These calculations clearly suggest that α -helical peptides may use their C-terminal amino acid as a relay station even in the absence of an aromatic or sulfur-containing side chain, and they point out the importance of considering peptide bonds as possible relay stations. Schlag *et al.*^{76,77} concluded from their investigations on electron hole migration across polypeptide chains that ET takes place via a hopping mechanism. However, they stress the importance of the peptide conformation in these hopping processes. Quantum mechanical calculations have shown that the hopping of the charge is strongly connected to the alignment of the CO groups. Therefore, in their opinion, efficient ET only takes place in very few conformations, which are not the ones typically found for peptides. Since mechanical rotation of the peptide chain along the Ramachandran plot proceeds very fast, Schlag *et al.* suggested that the first step of the ET process are the dihedral motions between neighboring amino acids followed by the hopping reaction in a second step.

Figure 27 Kimura and coworkers found only a weak distance dependence on ET processes through α -helical peptides with ferrocene as electron donor, which are self-assembled on gold. They explain this phenomenon by proposing a hopping mechanism, which uses the amide bonds as stepping stones.

Despite these strong indications that amides might act as relay stations in certain peptides, this suggestion is still controversially discussed in the literature, and several publications stating the opposite opinion can be found. For instance, Polo *et al.*⁷⁸ carried out experiments with poly-Aib structures, using either *p*-cyanobenzamide or phthalimide radical anions as electron donor and a peroxide as electron acceptor. They synthesized peptides with different numbers of Aib units, confirmed that all these peptides form 3₁₀-helices, and carried out electrochemical investigations in order to answer the question whether the ET proceeds via hopping or superexchange. They concluded that in their case, ET takes place via a superexchange mechanism and that the hydrogen bonds of a 3₁₀-helix play an important role in the ET reaction. Dey *et al.*⁷⁹ addressed the question by carrying out ET measurements with peptide films on gold surfaces. They prepared a series of collagen mimics with proline–hydroxyproline–glycine repeating units, a ferrocene at the N-terminus and a thiol-functionalized cysteine at the C-terminus. The peptides, which show a strong tendency to form collagen-like triple helices, were then immobilized on gold surfaces and electrochemical measurements were carried out. In their experiments, a weak distance dependence of the ET was observed, which is usually taken as an indication that ET proceeds via a hopping mechanism. However, the authors interpret this observation as result of a tunneling with a low β -value due to increased coupling through hydrogen bonds. They further argue that it has been reported that ET through H-bonded helical peptide films is strongly influenced by the dynamics of the peptide, and they suggested that a dynamically modulated tunneling mechanism takes place in their collagen mimics. The role of amides as stepping stones in ET processes through peptides is therefore still a highly discussed topic with a lot of ongoing research in various groups (see **Oxidative Damage to Proteins**).

7 THE RNR AS PARADIGM FOR ET IN BIOLOGICAL SYSTEMS

The enzyme RNR transforms nucleotides to deoxyribonucleotides and therefore serves as a link between the RNA and DNA world (see also Figure 3).⁶ It exists in three different forms, all of them using a thiyl radical of a cysteine side chain

for the activation of the ribose moiety. The major difference between them is the way this radical is generated leading to the division in three different classes according to this initialization step.⁸⁰ We will discuss class I RNRs since this enzyme class has become the paradigm for long-range ET in biological systems.⁶ The active cysteine radical in the α^2 -subunit is generated from cysteine (Cys⁴³⁹) that donates an electron to a tyrosyl radical (Tyr¹²²) in the β^2 -subunit over 35 Å. On our human scale, an average-sized human being of 1.70 m height would have to run about 1050 km or 25 marathons in order to achieve the same performance as a 4.6×10^{-15} m small electron that travels over 35 Å. This distance corresponds to a timescale of hours to years for the ET assuming single-step tunneling. Since a single turnover of the RNR only needs about 200 ms, the ET between the two amino acids must be at least that fast.⁸¹ An electron relay mechanism was first proposed by Uhlin and Eklund,⁸² which is based on a docking model of the two subunits as well as the conservation of amino acid residues in the primary sequence alignment, leading to a distance of about 35 Å between the donor and acceptor. This long distance between the two residues is further supported by pulsed electron–electron double resonance spectroscopy.⁸³ A putative PCET pathway for the electron transport from the Tyr¹²² radical to Cys⁴³⁹ is shown in Figure 28, which is based on results of Stubbe *et al.*^{6,84} on site-directed mutagenesis, the incorporation of unnatural amino acids and spectroscopic examination of transient radical intermediates.

The electron hopping is initiated by the oxidation of Tyr¹²² by the diferric cofactor. Its assembly requires Fe(II) binding and the reduction of O₂ to H₂O and is suspected to be endorsed by Trp⁴⁸. Moreover, this tryptophan residue is a key player in the ET process since its replacement by a nonredox active amino acid led to a breakdown of the ET resulting in inactive mutants. Asp²³⁷ and His¹¹⁸, which are also conserved in all species, are hydrogen bonded to Trp⁴⁸. Asp²³⁷ is suspected to play a role as proton shuttle to Trp⁴⁸ (Figure 14). This hypothesis was strengthened by site-directed mutagenesis experiments, which showed that the replacement with another acidic side chain (glutamic acid) is tolerated, while the replacement with alanine or asparagine knocks out catalytic activity.⁸⁴ Tyr³⁵⁶ has been postulated to modulate ET between the two

Figure 28 ET pathway and proton shuttles in ribonucleotide reductases class Ia. The generation of the active cysteine radical, which is responsible for the catalytic activity of this enzyme, is achieved by donation of an electron from Cys⁴³⁹ to a tyrosine radical (Tyr¹²²) over a distance of 35 Å. Along this pathway, the electron hops over several stepping stones, including a number of tyrosines as well as a tryptophan.

subunits of the enzyme, more precisely, between Trp⁴⁸ and Tyr⁷³¹. The exact location of this stepping stone is not specified since it has not yet been located in crystal structures. Nevertheless, its conservation together with experimental evidence based on mutagenesis studies and the incorporation of unnatural amino acids emphasize the role of Tyr³⁵⁶ as part of the ET pathway. It is suggested that on oxidation, the proton of Tyr³⁵⁶ is transferred directly

into the bulk solution. This is not the case for the last part of the pathway, from Tyr⁷³¹ over Tyr⁷³⁰ to Cys⁴³⁹, for which theoretical calculations⁴⁵ as well as mutations with redox-inactive phenylalanine predict a proton-dependent ET or a direct H-transfer. Furthermore, experiments with 3-aminotyrosine that served as thermodynamic trap showed the generation of the 3-aminotyrosine radical by X-band electron paramagnetic resonance spectroscopy.^{85,86}

Figure 29 Schematic representation of the proposed mechanism for the transformation of ribonucleotides to deoxyribonucleotides in ribonucleotide reductases (26 → 32).

With the generation of the thiyl radical, the catalytic turnover for the transformation of ribonucleotides to deoxyribonucleotides is initiated at the active site.^{6,80} Besides the initiating Cys⁴³⁹, two additional cysteine residues (Cys⁴⁶² and Cys²²⁵) as well as a glutamic acid residue (Glu⁴⁴¹) are involved in catalysis (Figure 29). The Cys⁴³⁹ radical abstracts a hydrogen atom from the 3'-carbon of the ribose moiety **26** forming a substrate radical **27** in a general base catalyzed reaction.⁸⁷ Responsible for the general base catalysis is the glutamate residue, which is perfectly positioned for the deprotonation of the 3'-hydroxy group. Cleavage of the β -C–O bond in **27** yields radical **28** in a fast reaction step. Subsequent hydrogen abstraction from Cys⁴⁶² leads to ketone **29** and a disulfide radical anion. In the following subsequent reduction of **29** over its protonated form **30** to the α -hydroxyl radical **31**, glutamic acid acts as general acid catalyst, making the reduction of the carbonyl group by the disulfide radical anion thermodynamically feasible.⁸⁷ The final step then yields the desired deoxyribonucleotide **32** together with the regenerated Cys⁴³⁹ radical.

Recently, it was discovered that class Ib RNRs contain an active dimanganese(III)-tyrosine radical cofactor instead of the diferric-tyrosine radical cofactor present in class Ia RNRs.^{88,89} Both types have identical metal-binding sites. Since Mn(II) is bound more tightly than Fe(II) but cannot be converted to an active tyrosine radical containing form, the question arises, how correct metallation of metalloenzymes is ensured by the cell. The answer to this question is a topic of current discussion and experimental tests, and further elucidation are needed in order to understand the metal selectivity of class Ia and Ib RNRs *in vivo*.⁹⁰

8 ELECTRONIC MATERIALS

With the goal of minimizing the size of electronic devices, several research groups now focus on organic molecules to substitute the classical semiconductors (Si, Ge, GaAs, etc.).⁹¹ The most important advantages of organic molecules over these classical semiconductors for applications ranging from biomedical equipment and sensors to TV systems are the lower current and power operation, the cheaper and simpler fabrication as well as their mechanical flexibility. Therefore, in recent years,

a number of research groups started working on biomolecules (DNA and peptides/proteins) as electronic devices, investigating ET through single molecules rather than the bulk conduction of organic polymers, where the common theories focus on charge migration between neighboring polymers. The aim of this research is not directed toward the development of more flexible TV screens, but the main focus lies in the field of medicine (e.g., biosensors), of molecular electronics and nano-electromechanical systems (NEMS) as well as in the search for conductive nanowires.

In 2005, Yemini *et al.*⁹² developed peptide nanotube-based electrodes, which could be successfully employed as amperometric biosensors. It was found earlier that the diphenylalanine core of the β -amyloid polypeptide can self-assemble to form tubular structures. These self-assembled peptides were then immobilized on gold electrodes, and the electrochemical properties were investigated with regard to the detection of NADH and glucose. The analysis of NADH provides the opportunity to analyze ethanol, whereas the glucose detection is needed for the diagnosis of diabetes as well as in food industry. It could be shown by amperometric response measurements that this system is indeed a promising biosensor.

Rinaldi *et al.*⁹³ used the electron-transfer protein azurin in order to produce biomolecular rectifiers. On a Si/SiO₂ substrate, two gold nanoelectrodes were interconnected, with a gap of 50–100 nm that contained a monolayer of immobilized copper-containing azurins. The resulting rectifiers were then tested by measuring *I*–*V* (current–voltage) curves and were found to operate at room temperature and in the presence of air and to exhibit a rectification ratio of 500 at 10 V. The replacement of the copper ions by zinc as well as devices without any metal ions showed that copper seems to be responsible for the ET, as a drop in the current flux was detected in the zinc-containing proteins and no conductance could be found in the metal-free device. Since the authors also observed a sensitivity of this rectifier to the atmosphere composition, they suggest that its suitability as a biosensor might also be exploited.

In 2004, Kimura and coworkers developed a molecular photodiode, which can switch the photocurrent direction (Figure 30).⁶⁵ They synthesized α -helical peptides with L- or D-leucine/Aib repeating

Figure 30 Kimura *et al.* developed a photoswitchable diode by coassembling α -helical peptides with opposing dipole moments and two different photosensitive groups on a gold surface. On excitation with different wavelengths (351 or 459 nm), a photocurrent in opposing directions, which is explained by the direction of the overall dipole moment, could be observed.

units, with one of them carrying a photosensitive group at the C- and a disulfide group at the N-terminus and the second one having a different photosensitive group at the N- and a disulfide group at the C-terminus. These peptides were then coassembled on a gold surface via an Au–S linkage, resulting in monolayers, containing peptides with opposite dipole moments. On excitation of the two different photosensitizers, which were addressed independently of each other (the one at 351 nm and the other at 459 nm), a photocurrent in opposite directions could be observed. Therefore, Kimura *et al.* developed a photodiode whose photocurrent

direction can be switched by changing the wavelength of the irradiating light.

Research in this area of SAMs has also been carried out by several groups, including Kraatz, Zhou and coworkers⁹⁴ and Strong and Moore,⁹⁵ with self-assembled peptides on gold surfaces. They investigated ET with regard to applications in molecular electronics, sensors, and catalysis. It should be noted that in all these experiments, α -helical peptides were used. This already shows that the conductance of peptides is highly dependent on several factors, including their secondary structure, and thus also their amino acid sequence, as well as pH, overall length, and the amount of water present, indicating the importance of protons in these processes.⁹¹

Apart from using SAMs, research with single molecules has also been carried out. However, investigating the ET properties of single biomolecules is far more complicated than studying the same phenomenon with SAMs. First of all, methods for the connection of a single molecule to the electrodes as well as suitable characterization methods have to be developed.⁹⁶ Furthermore, it is desirable to study biomolecules in their natural conformations. Therefore, it is required to expose the molecules to solvents and to control the pH of the surrounding medium.⁹⁷ Tao and coworkers have carried out investigations with simple peptides, consisting of one to three amino acids and different numbers of amine and/or carboxyl groups.⁹⁸ All these peptides contained thiol-functionalized termini in order to covalently attach them to gold electrodes (Figure 31). The attachment of a single molecule to the gold electrodes was achieved by repeatedly moving the gold electrode in and out of contact with a gold substrate in a diluted solution of the peptide. The control of the molecular junctions was done using a piezoelectric transducer. In accordance with other studies, it was shown that the ET through these single peptides proceeds via a tunneling mechanism with decay constants β varying between 0.7 and 0.9 Å.^{96,97,99} The three different devices were then tested for their pH dependence by recording conductance histograms at different pH values (pH 1.5, 7.4, and 13.0). The strong pH dependence found in these systems was explained by deprotonation/protonation of the amine/carboxyl groups, which influences the tunneling barrier for electrons and therefore increases the conductance at low pH values.

Figure 31 Tao and coworkers investigated the pH dependence of ET through single molecules. They attached peptides of different lengths and/or different numbers of acidic and basic groups to gold electrodes and measured the ET at different pH values.

Apart from the influence of the pH value, a change in conductance has also been reported on the binding of metal ions. Tao and coworkers synthesized peptides of different lengths, containing cysteamine, cysteine, and glycine and then covalently attached single molecules to gold electrodes and measured I - V curves of these peptides with and without the presence of metal ions (Cu^{2+} , Ni^{2+} , Zn^{2+} , K^+ , and Na^+).¹⁰⁰ For Cu^{2+} and Ni^{2+} , they found a large dependence of the conductance on binding to the metal ions. The exact value depended on the length and sequence of the peptide as well as on the metal ion which was used for complexation. An increase in conductance up to a factor of 320 was observed for the sequence cysteamine–diglycine–cysteine complexed to Cu^{2+} . The increased conductance is explained by two factors. First, the complexation of the metal ion to the deprotonated peptide affects the charge distribution and therefore the tunneling barrier. However, this effect was found not to be large enough to explain the large increase in conductance. The authors explain this significant change by an altered conformation as well as by electrons being transported through the chelate bonds instead of the peptide backbone. The findings described in this publication not only give rise to molecular wires with

higher conductance values, but they also suggest a method to study molecular recognition processes on a single-molecule basis, since the change in conductance depends on the complexed metal ion.

9 CONCLUSION

ET in peptides and proteins is a hot topic of ongoing research. A breakthrough for the understanding of long-distance ET is the discovery of the hopping mechanism, which describes long-range ET by several short and therefore fast ET steps. This charge diffusion between relay stations dramatically reduces the influence of the overall distance on the ET rate. Amino acids with low redox potentials can act as stepping stones, and recent experiments have revealed that not only aromatic but also sulfur-containing aliphatic amino acids function as relay stations. The reactive intermediates in these ET reactions are radicals and radical cations.

It remains to be seen whether amide bonds of peptides are also stepping stones under certain conditions. Another area for further research is the influence of dipole moments on ET rates and the significance of charges or Lewis acids for these processes. ET is often coupled with a proton shift, which is used by nature to monitor enzymatic reactions. Future work will also reveal whether certain natural or unnatural peptides can be applied as electronic materials.

Radical Enzymes

Wolfgang Buckel^{1,2} and Bernard T. Golding³

¹*Fachbereich Biologie, Philipps-Universität, Marburg, Germany,* ²*Max-Planck-Institut für terrestrische Mikrobiologie, Marburg, Germany* and ³*School of Chemistry, Newcastle University, Newcastle upon Tyne, UK*

1 INTRODUCTION

The term *radical enzyme* describes those enzymes that catalyze reactions in which species with an odd number of electrons participate. Such species were classically described as free radicals,¹ but this is confusing because of the two meanings of the word free, although the definition originally applied to radicals was in the sense of a free, that is, nonbonded, electron. In enzymes, radicals cannot be free, in the sense of not being shackled, because they are usually bound to the protein.² The mode of binding is either as a component of a polypeptide chain as with glycyl and tyrosyl radicals or as a reactive intermediate, which is anchored to an enzyme by noncovalent interactions.

It seems paradoxical that some enzymes with their multitude of functional groups are able to survive in the presence of radicals, which are renowned for their high reactivity and consequent short lifetime. However, this overlooks the possibility that enzymes restrict the movement of radicals and therefore their ability to attack distant and even neighboring groups within the protein. Furthermore, dimerization is impeded by encapsulation of the radical. However, the reactions of radicals with some external agents, notably the small diradical dioxygen, cannot be avoided with otherwise long-lived radicals, for example, glycyl radicals in a special class of radical enzymes. With radicals that are

intermediates in catalytic pathways, their short lifetimes and low concentrations enable capture by dioxygen to be minimized.

Two classes of radical enzymes have emerged: one in which radicals are generated and consumed, for example, biotin synthase, and the other in which the radicals are recycled, for example, coenzyme B₁₂-dependent mutases. With biotin synthase, *S*-adenosylmethionine (SAM) serves as precursor of the 5'-deoxyadenosyl (adenosyl) radical, which irreversibly abstracts a hydrogen atom from dethiobiotin³ to afford 5'-deoxyadenosine and a substrate-derived radical that reacts with a sulfur of the [2Fe–2S] cluster. Conversely, with the coenzyme B₁₂-dependent mutases, the 5'-deoxyadenosyl radical also abstracts a hydrogen atom from a substrate molecule to give the methyl group of 5'-deoxyadenosine and a substrate-derived radical. However, after rearrangement of the substrate radical to a product-related radical, this becomes a product molecule by regaining a hydrogen atom from 5'-deoxyadenosine, thus regenerating the 5'-deoxyadenosyl radical.

This article succeeds earlier reviews, which focused on radical enzymes in anaerobic organisms.⁴ As in these reviews, we will primarily discuss enzymatic reactions via intermediate radicals. We will also refer to processes with one-electron transfers, when these are essential to the catalytic

reaction, for example, for 2-hydroxyacyl-CoA dehydratases and benzoyl-CoA reductase (BCR).

1.1 The Primary Radicals of Biology

A recent review classified biologically relevant radicals as reactive oxygen, nitrogen, sulfur, and carbon species.⁵ The reactive oxygen species (ROS) include the radicals superoxide ($\text{O}_2^{\cdot-}$), hydroxyl ($\cdot\text{OH}$), and carbonate ($\cdot\text{OCO}_2^-$), while nitric oxide ($\cdot\text{NO}$) is the principal reactive nitrogen species. These radicals are discussed elsewhere and are not covered here (see **Oxidative Damage to Proteins**). Thiyl radicals ($\text{RS}^\cdot$) are generated when thiols act as scavengers of other radical species (e.g., ROS) and are also active species in some of the radical enzymes described below. In this article, the focus is on carbon radicals that are integral to the mechanisms of certain enzymes. These radicals are either derived from a cofactor (e.g., coenzyme B_{12} , the precursor of the 5'-deoxyadenosyl radical) or substrate molecule (e.g., glutamate, the precursor of the 4-glutamyl radical) or exist within a polypeptide chain (glycyl radical). Such radicals may be relatively long-lived by virtue of their encapsulation within enzymes and can be characterized by electron paramagnetic resonance (EPR) and electron nuclear double resonance spectroscopy (ENDOR). Carbon radicals formed as a consequence of oxidative damage to proteins are not discussed here. The iron-oxy radical species used by *P450* mono-oxygenases (CYP450s) and the intermediate carbon radicals in CYP450 oxidations are detailed elsewhere. Single-electron transfer processes as found in photosynthesis and respiration, as well as mechanisms protecting against ROS, for example, Refs 6 and 7, are not covered here.

1.2 Mechanisms of Radical Enzymes and Generation of Radicals

The principal steps in the catalytic pathways of radical enzymes leading from substrate to product are (i) generation of an initiating radical either from a suitable molecule (e.g., 5'-deoxyadenosylcobalamin (adenosylcobalamin, coenzyme B_{12}), SAM) or from a relatively stable storage radical (e.g., glycyl radical); (ii) reaction of this radical with a substrate molecule to give a substrate-derived radical; (iii) transformation of the substrate-derived radical

into the product-related radical; and (iv) conversion of the product-related radical into a product molecule, which may regenerate and hence recycle the initiating radical. In most of the SAM radical enzymes, however, the 5'-deoxyadenosyl radical is not regenerated. This is because it abstracts a hydrogen atom either from the substrate directly or from a protein's conserved glycine residue, which is converted into an active radical enzyme. 5'-Deoxyadenosine is released and the product survives either as a radical (e.g., with glycyl-radical enzymes) or is converted into a nonradical species. We can distinguish primary "SAM radical enzymes" from secondary "glycyl-radical enzymes," which are active without SAM.

The generation of radicals can be achieved by homolysis of a σ -bond, which necessarily produces two radicals. When coenzyme B_{12} is bound to an enzyme partner, addition of substrate triggers homolysis of the weak Co–C σ -bond (bond dissociation energy $\sim 130 \text{ kJ mol}^{-1}$) and affords cob(II)alamin and the 5'-deoxyadenosyl radical. This bond homolysis is accelerated by approximately 10^{12} -fold as a consequence of contributions from binding energy and conformational change.⁸ One-electron transfer from ferredoxin or flavodoxin to SAM effects homolytic fission of its S–CH₂ bond to give methionine and the 5'-deoxyadenosyl radical. Barker⁹ called SAM the "poor man's adenosylcobalamin" because of the structural simplicity of SAM compared to coenzyme B_{12} . This epithet was inverted by Perry A. Frey to "rich man's adenosylcobalamin," so as to express the multitasking of SAM.¹⁰

An alternative mode of generation of a radical is by reductive one-electron transfer. This may occur to a carbonyl group of a coenzyme A (CoA) thiol ester or to an amide (e.g., thymidine) with formation of a nucleophilic ketyl radical. The energy for these processes, where necessary, derives either from adenosine triphosphate (ATP) hydrolysis or from light, respectively. Acyl-CoA dehydrogenases and 4-hydroxybutyryl-CoA dehydratase may form ephemeral ketyl radicals by deprotonation—one-electron oxidation—deprotonation. Finally, the "pseudo radical enzymes" pyruvate:ferredoxin oxidoreductase and methyl-CoM reductase can effect two-electron cleavage of a C–C or C–H bond, which is followed by stepwise one-electron oxidation or reduction.

There are only a few SAM-dependent enzymes in which SAM is recycled after each turnover, with the most extensively studied example being lysine-2,3-aminomutase.¹¹ Although the formation of active ribonucleotide reductase (RNR), class I, is irreversible, the tyrosyl radical is recycled after each turnover of substrate to product. With coenzyme B₁₂-dependent enzymes, the coenzyme's Co(III)–C σ -bond acts as a storage entity for the active 5'-deoxyadenosyl radical and cob(II)alamin. Glycyl-radical enzymes store the glycyl radical, which reacts with a cysteine thiol to give the active thiyl radical. In 2-hydroxyacyl-CoA dehydratases, storage is via a β -[4Fe–4S]⁺ cluster, while the active form is an α -[4Fe–4S]⁺ cluster. Finally, 4-hydroxybutyryl-CoA dehydratase uses flavin adenine dinucleotide (FAD) with [4Fe–4S]²⁺ for storage, while the active species are FAD semiquinone, [4Fe–4S]^{2+/1+}, and possibly a substrate-based radical.

2 SPECIFIC RADICAL ENZYMES

2.1 Ribonucleotide Reductases

The conversion of ribonucleotides to 2'-deoxyribonucleotides, the monomers required for the construction of DNA, is catalyzed by radical enzymes called *RNRs*, of which there are three distinct kinds (classes I, II, and III) depending on the host organism.

Class I enzymes, which are further subdivided into Ia, Ib, and Ic, are found in aerobic organisms such as *Escherichia coli* (class Ia) and are widely distributed among eubacteria, eukaryotes, bacteriophages, and viruses.^{12,13} Inhibitors of some of these

enzymes are potential chemotherapeutic agents.¹⁴ Human RNR belongs to class I, specifically the subclass Ia. The catalytic activity of RNR depends on the combination of a tyrosine residue with either a di-iron-oxo species (class Ia) or a di-manganese-oxo entity (class Ib). Class Ic enzymes, for example, the RNR from *Chlamydia trachomatis*, contain an Fe(III)–(O)₂–Mn(IV) unit. For each subclass, there is an array of tyrosines (Figure 1) that act as radical carriers (see **Electron Transfer in Peptides and Proteins**). Ultimately, one particular tyrosine oxy radical abstracts a hydrogen atom from a conserved cysteine leading to a cysteine thiyl radical responsible for activating ribose for reduction (Figure 1).

Class II enzymes are used by some algae, archaeobacteria, and eubacteria (e.g., *Lactobacillus leichmannii*) that are anaerobic by nature but can survive when exposed to dioxygen. These enzymes harness the adenosyl radical from coenzyme B₁₂ and it is this species which is used to generate a thiyl radical from an active site cysteine.¹⁶ As with the class I enzymes, the derived thiyl radical initiates the reduction of ribose.

Class III enzymes are strictly anaerobic and exemplified by some archaeobacteria and eubacteria. They employ a relay system, whereby the adenosyl radical from SAM, rather than coenzyme B₁₂, abstracts a hydrogen atom from a conserved glycine in the protein's polypeptide chain. The resulting glycyl radical, in turn, converts an active site cysteine into a thiyl radical.¹⁷

Despite the remarkable diversity among RNRs with respect to their radical-generating machinery, although all converge on an intermediate cysteine thiyl radical, they pursue a common mechanism for the critical steps of the catalytic pathway, that is, the abstraction of the 3'-hydrogen atom

Figure 1 Pathway for proton-coupled electron transfer in *Chlamydia trachomatis*. [(we thank Dr., J. M. Bollinger for a copy of this illustration). Reproduced from Ref. 15. © American Chemical Society, 2010.]

of ribose coupled to reductive elimination of the 2'-hydroxyl group (see **Theoretical Studies of Radical Enzymes**).

2.1.1 The Radical-Generating Machinery of RNRs

Structural biology and spectroscopic techniques (primarily EPR and ENDOR) have provided a wealth of information on the active sites of all classes of RNR.

The *E. coli* class Ia enzyme is composed of subunits R1 and R2, also labeled α and β , respectively. The 1 : 1 complex ($\alpha_2\beta_2$) of the homodimeric subunits is believed to be the catalytically active form of this RNR with the nucleotide-reducing activity being located in α , while the di-iron-tyrosyl radical (Y122) cofactor resides in β .¹⁸ The identity of the oxygen species in the di-iron part has been controversial.^{18–20} This entity is formed by reaction between a Fe(II)–Fe(II) dimer and dioxygen generating a Fe(III)–Fe(IV) pair with additional oxygen ligands. Examination of this oxygenated di-iron species with 35-GHz pulsed ENDOR suggested the presence of a terminal hydroxide ligand bound to Fe(III) and one or two oxo bridges between the Fe centers.¹⁸ Communication between the α and

β sites could be via proton-coupled electron transfer over circa 35 Å assisted by intervening tyrosines and a tryptophan and leading to the formation of a thiyl radical by abstraction of a hydrogen atom from C439 by the tyrosyl radical. The *E. coli* RNR serves as a reference point for all RNRs, with the class II and III enzymes exhibiting a structurally similar protein to the α_2 subunit. However, the circuitous electron transfer with the *E. coli* RNR is not a feature of class II and III RNRs, which rely on the adenosyl radical as the focal point of the catalytic apparatus.

X-ray analysis of an RNR from *Corynebacterium ammoniagenes* identified the enzyme as belonging to class Ib with a manganese dimer bridged by an oxo/hydroxo group close to a tyrosine (Y115).²¹ The oxidation of the dimer was achieved with hydrogen peroxide derived by reduction of dioxygen with a flavoprotein.²² A theoretical study of the class Ic RNR from *C. trachomatis* identified the manganese center of the Fe(III)–(O)₂–Mn(IV) unit as that serving as oxidant.²³

A detailed examination of the class II RNR from *Thermotoga maritima* gave new insights into the role of coenzyme B₁₂.¹⁶ The binding of the cobalamin to the RNR active site guards the intermediate cysteinyl radical and substrate radical. A hydrogen bond between the substrate α -phosphate

In the structure alongside, R = 5'-deoxyadenosyl is coenzyme B₁₂ (also called 5'-deoxyadenosylcobalamin or simply adenosylcobalamin), whilst R = CN denotes cyanocobalamin (vitamin B₁₂). All cobalamins contain 5,6-dimethylbenzimidazole, which is the so-called 6th ligand to cobalt. Substances containing the corrin ligand, i.e. the planar 14 electron π -system embracing cobalt in the above structure, are also called corrinoids.

Figure 2 Structure of coenzyme B₁₂ and other cobalamins.

Scheme 1 Outline mechanism for *E. coli* RNR.

and *e*-propionamide of adenosylcobalamin (see lettering in Figure 2) locks the coenzyme in place. In addition, a conformational change in the ribose ring of adenosylcobalamin enables transfer of a hydrogen atom from ribose (H-3') to the cysteine thiyl radical.

2.1.2 Mechanism of RNRs

The nonenzymatic reductive cleavage of a secondary alcohol to an alkane requires conversion of the hydroxyl group to a better leaving group (e.g., sulfonate ester) and reduction with a powerful hydride-transfer agent (e.g., lithium aluminum hydride). An analogous pathway with RNR is implausible because there is no evidence of phosphorylation of the 2'-hydroxyl group and reducing cofactors such as NADH for the ribose reduction are not involved. However, the facile acid- or base-catalyzed elimination of a hydroxyl group *beta* to a carbon radical center has long been known and was originally suggested²⁴ as being relevant to the mode of action of diol dehydratase, the reaction pathway of which resembles that of RNR, thus justifying the soubriquet “eliminase” for both enzymes. Detailed knowledge of the protein, theoretical studies of putative reaction pathways, and the use of inhibitors have led to the mechanism shown in Scheme 1 for the RNR from *E. coli*.^{14,18,25,26}

The initial step is the abstraction of a hydrogen atom from C-3' of the ribose unit by a cysteine thiyl radical (from C439) to afford a substrate-derived C-3' radical. Concomitant with partial deprotonation

of the 3'-hydroxyl group by E441, elimination of the 2'-hydroxyl group facilitated by partial protonation by C225 affords an enoxy radical; compare the mechanisms of diol dehydratase (Section 2.2.3) and the 2-hydroxyacyl dehydratases (Section 2.4). Sequential reductions utilizing cysteine residues (C225 and C462), which generate a transient disulfide radical anion,²⁷ lead to deoxyribose with a radical center at C-3'. This is quenched by transfer of hydrogen atom from C439, which generates 2'-deoxyribose and the starting C439 thiyl radical. For recent discussions on specific aspects of Scheme 1, see Refs 28 and 29.

Similar mechanisms apply to all other RNRs with an additional caveat for the coenzyme B₁₂-dependent RNR. The acidity of a cysteine thiol ($pK_a \approx 8$) results in exchange of hydrogen between this thiol group, the 5'-methylene group of coenzyme B₁₂, and water.³⁰ Furthermore, incubation of this RNR with adenosylcobalamin containing one deuterium atom at C-5' (*R/S* ratio = 3 : 1) gave an *R/S* ratio of 1, indicating that the cobalt–carbon σ -bond is homolyzed to a 5'-deoxyadenosyl radical and cob(II)alamin reversibly, thus enabling rotation about the C-4'/C-5' bond.

2.2 Coenzyme B₁₂-Dependent Enzymes

2.2.1 Introduction

Coenzyme B₁₂ (Figure 2) operates with two types of radical enzymes, the “base-on” (see

footnote *c* of Table 1 for the definitions of “base-on” and “base-off, his-on”) eliminases (e.g., propane-1,2-diol dehydratase)³¹ and the “base-off, his-on” mutases,³² with the latter group being subdivided into carbon skeleton mutases (e.g., glutamate mutase)³³ and amino mutases (e.g., β -lysine-5,6-aminomutase,³⁴ see Table 1 for a summary). Some authors refer to classes I, II, and III of coenzyme B₁₂-dependent radical enzymes. The carbon skeleton mutases are placed in class I, the eliminases in class II, and the amino mutases in class III, but this classification seems illogical and conveys no sense of the enzyme’s purpose. Coenzyme B₁₂’s radical enzymes are found mainly in anaerobic bacteria, except for methylmalonyl-CoA mutase, which mediates the oxidation of propionate in animals (but not insects) and syntrophic bacteria as well as the formation of propionate in propionibacteria.³⁵ Recently discovered CO₂ fixation pathways use the carboxylation of propionyl-CoA to methylmalonyl-CoA with a subsequent rearrangement to succinyl-CoA.^{36,37} Furthermore, the reductive carboxylation of crotonyl-CoA yields (*S*)-ethylmalonyl-CoA, which is epimerized and rearranged by a novel mutase to (*S*)-3-methylsuccinyl-CoA.³⁸

Since the discovery of the first B₁₂-dependent radical enzymes some five decades ago,^{39,40} their study has passed through several phases in the quest for mechanistic understanding at atomic precision. In the early phase (up to the 1980s), most of the catalytic reactions were defined and experimental and theoretical model systems were developed, some of which have survived the test of time.⁴¹ In the middle phase, the first crystal structures emerged for methylmalonyl-CoA mutase⁴² and diol dehydratase,⁴³ high level calculations made a further impact^{44,45} and mechanisms were refined. Finally, post 2000, the field matured with crystal structures being available for all the eliminases, the carbon skeleton mutase glutamate mutase⁴⁶ and for β -lysine aminomutase.³⁴ The detailed study of isotope and tunneling effects^{47,48} and the further application of theoretical calculations⁴⁹ have provided ever more detailed mechanistic insights. Many books and reviews have traced the evolution of the subject.^{50–55}

2.2.2 Overview of Mechanisms

The fundamental philosophy for all coenzyme B₁₂-dependent reactions is that homolytic fission of the coenzyme’s Co–C σ -bond is a prelude to the conversion of substrate to product. Although this Co–C bond is relatively weak (bond dissociation energy circa 130 kJ mol^{–1}) and the coenzyme is rather stable in water at 30 °C ($\tau_{1/2}$ 1.9 years),⁵³ it is assumed that the binding to the enzyme partner and the arrival of a substrate molecule initiates cleavage of the Co–C bond. The mechanistic basis for this proposal is that the cob(II)alamin–5′-deoxyadenosyl radical pair enables some specific tighter binding interactions. One such interaction is a possible hydrogen bond between the 3′-oxygen of ribose and H-19 of the corrin. This was suggested by calculations that indicated that the 3′-oxygen approaches H-19 within 3.5 Å and that the resulting stabilization amounts to 30 kJ mol^{–1}.⁵⁶ Other evidence for beneficial postcleavage interactions has come from a careful examination of the coenzyme B₁₂-binding site in ethanolamine ammonia lyase (EAL).^{57,58}

After the formation of cob(II)alamin and the 5′-deoxyadenosyl radical, hydrogen atom abstraction by the adenosyl radical from a substrate molecule (SH) generates 5′-deoxyadenosine and a substrate-derived radical (S′), which is converted into a product-related radical (P′) and hence product (PH) (Scheme 2). Abstraction of a hydrogen atom from relatively inert substrate carbon centers indicates that radicals participate in the coenzyme B₁₂-dependent enzymatic reactions. Most convincingly, freeze-quench techniques and EPR spectroscopy, aided by the use of isotopically labeled substrates (e.g., ²H and ¹³C), have detected radical species for diol dehydratase,⁵⁹ EAL,^{60,61} 2-methyleneglutarate mutase,⁶² methylmalonyl-CoA mutase,⁶³ glutamate mutase,⁶⁴ lysine-5,6-mutase,⁶⁵ and ornithine mutase.⁶⁶

10. Ornithine-4,5-aminomutase (<i>Clostridium sticklandii</i>)	

^aThe natural or typical substrate + product are given.

^bSee Figure 2.

^cThe term *base-on* means that N-1 of the 5,6-dimethylbenzimidazole ligand (Figure 2) remains attached to cobalt; “base-off, his-on” signifies that the 5,6-dimethylbenzimidazole ligand is substituted by a histidine residue from the partner enzyme.

The complex signals observed were ascribed to cob(II)alamin interacting with an organic radical at a distance of 6–11 Å.

For the reversible reactions given in Table 1 (all mutases), substrate and product are synonymous

in principle, as reversion to substrate can occur via hydrogen atom removal from the so-called product to give the product-related radical, which reverts to the substrate-related radical. However, a distinction can be made (Table 1) on the

basis of the physiological direction of the reaction. For example, methylmalonyl-CoA mutase accepts (*R*)-methylmalonyl-CoA from the degradation of certain amino acids and converts it into succinyl-CoA, which enters the Krebs cycle. Whatever the direction of reaction catalyzed by the mutases, the role of 5'-deoxyadenosine is to trap the intermediate radicals (S' and P') with regeneration of the 5'-deoxyadenosyl radical.

An alternative to the concept of a stabilized cob(II)alamin-5'-deoxyadenosyl radical pair is that the homolysis of the Co–C bond is coupled to hydrogen atom abstraction from substrate.^{57,67} In this way, the formation of the essentially nonstabilized primary adenosyl radical is avoided, but only in some cases, by direct formation of a stabilized radical. For all the mutases provided in Table 1, at least one of the radicals is itself a primary organic radical and therefore no major energetic benefit from a concerted pathway is apparent.

Following the rupture of the coenzyme's Co–C bond and formation of a substrate-derived radical (or, alternatively, a product-related radical for the reversible reactions), the next challenge is to formulate satisfactory mechanisms for the interconversion of S' and P'. The precise mechanism of this process has been debated since the 1970s. For each of the enzymes provided in Table 1, the mechanism is influenced by the nature of the migrating group and the substituents in the vicinity of the radical centers. And for each group, be it eliminase, carbon-skeleton mutase, or amino mutase, there is a close correspondence of mechanism as discussed below.

The reactions catalyzed by the eliminases are all replicated by enzymes that are either dependent on SAM or a glycyl radical but are coenzyme B₁₂ independent (see below). In contrast, coenzyme B₁₂-independent mutases are unknown.³²

2.2.3 Eliminases

It was recognized early on that there were nonenzymatic precedents for the eliminases,²⁴ and in some respects, for the mutases (see the following section).⁶⁸ Chemical studies of 1,2-dihydroxyalkyl radicals and 2-amino-1-hydroxyalkyl radicals in the 1970s had shown the propensity of these species under acidic or basic conditions to eliminate water or ammonia, respectively, with the

formation in each case of a 2-oxoalkyl radical (Scheme 3). The authors of these studies were unaware of their possible relevance to the coenzyme B₁₂-dependent eliminases, which was pointed out with the introduction of a critical question: is there a bridged intermediate or transition state that enables conversion of a 1,2-dihydroxyalkyl radical or 2-amino-1-hydroxyalkyl radical into a 2,2-dihydroxyalkyl radical or 2-amino-2-hydroxyalkyl radical and hence a 2-oxoalkyl radical (Scheme 3).^{24,68} The “bridging” mechanism contrasts with the alternative and obvious fragmentation pathway whereby the 2-oxoalkyl radical is formed directly by elimination of water or ammonia. Since this initial period of conjecture, numerous studies have tried to unravel every possible nuance of the pathway.

The idea of a bridged species arose for diol dehydratase and glycerol dehydratase because of the startling discovery that hydroxyl at C-2 of propane-1,2-diol and glycerol migrates to C-1.^{69,70} This conclusion, based on evidence with ¹⁸O-labeled substrates, can only be accommodated by the fragmentation pathway if there is a recombination step giving an intermediate 2,2-dihydroxyalkyl radical. Irrespective of whether the 2,2-dihydroxyalkyl radical arises by the bridging or fragmentation-recombination route, why does the enzyme take the circuitous path rather than be satisfied with the 2-oxoalkyl radical initially derived from direct elimination? The mechanism proposed for RNR (Section 2.1, Scheme 1) includes a 1,2-dihydroxyalkyl radical that is supposed to undergo elimination of water to afford a 3-oxoalk-2-yl radical (ribose numbering), the radical center of which is quenched with formation of a 2-deoxy-3-oxoriboside. The reason for the formation of a 2,2-dihydroxyalkyl radical rather than a 2-oxoalkyl radical is that only the former is energetically primed to retrieve a hydrogen atom from 5'-deoxyadenosine.^{71,72} The analogous step with RNR requires the abstraction of a hydrogen from a cysteine thiol, which is circa 40 kJ mol^{−1} easier than abstraction from the methyl group of 5'-deoxyadenosine⁷⁴ and can be accomplished by the 3-oxoalk-2-yl radical.

The most advanced current mechanism for diol dehydratase and glycerol dehydratase provides a rather complete account of the roles of enzyme and coenzyme. Crystal structure analyses have confirmed that after fission of the Co–C bond of

Scheme 3 Alternative pathways for the decomposition of 1,2-dihydroxyalkyl radicals and 2-amino-1-hydroxyalkyl radicals derived from a 1,2-diol ($X = O$) and 2-amino-alcohol ($X = NH$): path (a) involves direct elimination of water or ammonia and path (b) proceeds via an intermediate bridged species.

coenzyme B_{12} , cob(II)alamin is at a distance of circa $10 \text{ \AA}$ from substrate and is therefore a spectator of radical chemistry initiated by the adenosyl radical.⁴³ The activation of diol dehydratase by a monovalent cation such as K^+ or NH_4^+ has long been known. The first electron density maps with the coenzyme surrogate cyanocobalamin bound to diol dehydrase were interpreted as showing that propane-1,2-diol acted as bidentate ligand to the potassium ion. Recently, the use of adenylylpentylcobalamin as an analog of coenzyme B_{12} led to a surprising re-interpretation, whereby it is Ca^{2+} that binds the diol, whereas K^+ anchors the coenzyme (Figure 3). Diol dehydratase was now termed a *metalloenzyme* because it is inhibited by ethylenediaminetetraacetic acid (EDTA), which extracts the calcium ion.⁷³ The substrate diol is positioned to give up a hydrogen atom to the adenosyl radical (see Figure 3, which shows, in addition, the four amino acid residues hydrogen bonded to the diol). It was proposed that the resulting 1,2-dihydroxyprop-1-yl radical rearranges to the 1,1-dihydroxyprop-2-yl radical by an intramolecular migration of the 2-hydroxyl group via a bridged intermediate (cf. Scheme 4, which shows this process for the 1,2-dihydroxyethyl radical from ethane-1,2-diol).⁷² This “push–pull” mechanism involves “partial protonation” of the migrating 2-OH and “partial deprotonation” of the nonmigrating 1-OH group. “Partial protonation” describes the ability of hydrogen bonding by protein functional groups to confer significant acid–base catalysis.⁷² Several theoretical calculations have supported this route as an energetically viable pathway, whereas the alternative fragmentation-recombination is more

costly (see data for glycerol dehydratase acting on glycerol (see **Theoretical Studies of Radical Enzymes**)).⁷⁵ Note that diol dehydratase is unusual in that both enantiomers of propane-1,2-diol react at similar rates. In Figure 3, the (*S*)-enantiomer is shown and it is the pro-*S* hydrogen that is removed. With the (*R*)-enantiomer, the pro-*R* hydrogen is removed.⁷⁶

EAL performs a similar reaction on vicinal aminoalcohols to that of diol and glycerol dehydratase on vicinol diols: the conversion of ethanolamine (2-aminoethanol) to ethanal and ammonia, and propanolamine (2-amino-1-propanol) to propanal and ammonia. A similar bridging pathway was proposed based on theoretical calculations.^{24,61,68,77} There is extensive spectroscopic evidence (EPR) for the proposed substrate-derived radical, that is, 2-amino-1-hydroxyethyl or 2-amino-1-hydroxyprop-1-yl.^{61,78} The crystal structure of EAL from *E. coli* containing a coenzyme B_{12} analog (cyanocobalamin or adenylylpentylcobalamin) showed a trimer of an $(\alpha\beta)_2$ dimer with a cobalamin molecule bound at the boundary of the α and β subunits.⁵⁸ The mode of binding of substrate 2-amino-1-propanol was via an array of hydrogen bonds similar to those observed with diol and glycerol dehydratase for their substrates. A critical issue is the protonation state of the substrate amino group, but this was not clearly resolved. Given that the ionization state of ethanolamine or propanolamine at physiological pH is the protonated species, it would be surprising if this were not the case for bound substrate, especially as a protonated substrate-derived radical is required for conversion to the product-related

Scheme 4 “Push–pull” mechanism for diol dehydratase with substrate ethane-1,2-diol.

radical. The detailed mechanism given by Shibata *et al.*⁵⁸ assumes a protonated substrate amino group arising from interactions with the side-chain groups of the neighboring residues Glu α 287, Asp α 362, and Gln α 162. All intermediates are shown as being anchored by an interaction between their hydroxyl group and a protonated arginine (Arg α 160), which takes the place of the metal ion in diol and glycerol dehydratase.

2.2.4 Carbon-Skeleton Mutases

The rearrangement of carbon skeletons catalyzed by coenzyme B_{12} -dependent carbon-skeleton mutases is an equilibratory process in which the less branched component dominates at equilibrium (Table 1). With the exception of glutamate mutase, the migrating groups all contain a $\text{C}=\text{C}$ or $\text{C}=\text{O}$ group that enables the rearrangement to be achieved via a bridged (cyclopropane)

intermediate (cf. the eliminases), as shown in Scheme 5 for 2-methyleneglutarate mutase equilibrating with (*R*)-3-methylitaconate.^{62,79} The mechanism shown is consistent with the observation that 2-methyleneglutarate mutase catalyzes the equilibration of (*E*)- and (*Z*)-2-(monodeuteromethylene)-3-methylsuccinate with the concomitant formation of (*E*)- and (*Z*)-2-(monodeuteromethylene)glutarate. The equilibration probably occurs via an intermediate 1-deuteromethylene-cyclopropane-1,2-dicarboxylate radical in which there is a low barrier to rotation around the σ -bond connecting the deuteromethylene radical-bearing group to the cyclopropane framework.⁷² This mechanism is also consistent with model studies, which showed the conversion of di-*t*-butyl 1-bromomethylene-cyclopropane-1,2-dicarboxylate, di-*t*-butyl 2-(methylene)-3-bromomethylsuccinate, and di-*t*-butyl 2-bromo-4-methyleneglutarate to di-*t*-butyl 4-methyleneglutarate when treated with triphenyltin hydride.⁸⁰ In this

Scheme 5 Intermediate radicals (**1b**, **2b**, and **3**) in the 2-methyleneglutarate mutase reaction (**1a** = 2-methyleneglutarate; **2a** = 3-methylitaconate).

case, the initially formed radicals correspond to each of those proposed as intermediates in the enzymatic reaction. All evidently converge on the thermodynamically most stable radical, that is, the di-*t*-butyl 2-(methylene)glutarate-4-yl radical, which is quenched to afford di-*t*-butyl 2-methyleneglutarate. The lack of a crystal structure for 2-methyleneglutarate mutase has hindered further progress.

The crystal structure for methylmalonyl-CoA mutase⁴² supports a similar mechanism to that described for 2-methyleneglutarate mutase, that is, via a bridged intermediate, the formation of which is facilitated by “partial protonation” of carbonyl oxygen by His244.⁷² Similar mechanisms can be written for isobutyryl-CoA mutase and

ethylmalonyl-CoA mutase. However, the remaining member of this group, glutamate mutase, is different from the others. This enzyme catalyzes the coenzyme B₁₂-dependent equilibration of (*S*)-glutamate with (2*S*,3*S*)-3-methylaspartate (Scheme 6). Now a bridged intermediate analogous to those discussed for the other mutases is not permissible. The possibility was considered that pyridoxal phosphate or other suitable species could generate an intermediate imine by combining with the α -amino group of substrate/product, thus enabling a bridged mechanism analogous to that proposed for lysine 2,3-aminomutase (see Section 2.3.1).⁸¹ However, no such species has been detected. This led to the postulate of a “fragmentation-recombination” mechanism (Scheme 6),^{82a} which was sustained by a

Scheme 6 Fragmentation–recombination mechanism for the equilibration of (*S*)-glutamate with (2*S*,3*S*)-3-methylaspartate catalyzed by coenzyme B₁₂-dependent glutamate mutase showing intermediate radicals.

critical experiment⁸³ in which the working enzyme was quenched by addition of trifluoroacetic acid. The fragments acrylate and glycine were retrieved in comparable quantities (0.06 mol each per mol of enzyme) from the resulting mixture. In an EPR study, the 4-glutamyl radical was detected as the dominant radical species for a reaction mixture that was arrested by cooling in liquid nitrogen.⁶⁴

The experiments described do not settle the mechanistic question because of the relatively high calculated energy barriers ($\geq 60 \text{ kJ mol}^{-1}$) that interconnect the intermediate radicals: 4-glutamyl, glycyl (+acrylate) and 3-methyleneaspartate (Scheme 6).^{44,84} The central issue concerns the participation of the nonstabilized, primary aspartate 3-methyl radical. To account for the involvement of such radicals in the mutase-catalyzed reactions, it was proposed that cob(II)alamin acts as a “conductor” that partially stabilizes the intermediate methylene radicals.³² The nature of this stabilization, if present, is unclear. What is clear is a sharp distinction between eliminases and mutases with respect to the distance between substrate/product radicals and cob(II)alamin (circa 10 Å in eliminases and circa 6 Å in mutases).

The structure of the complex between *apo*-glutamate mutase (components E & S) and

coenzyme B_{12} + its inhibitor (2*S*,3*S*)-tartrate revealed that transfer of a H atom to the 5'-deoxyadenosyl radical is controlled by pseudorotation of the cofactor's ribose ring (Figure 4).⁸⁵ On the basis of calculations, it has been suggested that the 3'-oxygen of the ribose moiety approaches H-19 of the corrin ring within 3.5 Å. This leads to the formation of a hydrogen bond that stabilizes the cob(II)alamin–deoxyadenosyl radical pair arising from fission of the Co–C σ -bond.⁵⁶

2.2.5 Aminomutases

β -Lysine-5,6-aminomutase and D-ornithine-4,5-aminomutase both catalyze the reversible shift of a terminal amino group to the next carbon atom with the aid of pyridoxal-5'-phosphate in addition to coenzyme B_{12} : (3*S*)- β -lysine yields (3*S*,5*S*)-3,5-diaminohexanoate; the enzyme also acts on (2*R*)- α -lysine to form 2,5-diaminohexanoate.^{34,65,86–88} In a similar manner, (*R*)-ornithine gives (2*R*,4*S*)-2,4-diaminopentanoate.^{66,89,90} The mechanisms of these reactions are analogous to that proposed for SAM-dependent lysine-2,3-aminomutase (see Section 2.3.1). The question arises as to why the

Figure 4 Pseudorotation of the cofactor's ribose ring controls the radical transfer in glutamate mutase. [Adapted from Ref. 85. © Wiley-VCH Verlag GmbH & Co. KGaA, 2001.]

shift of a terminal amino group requires coenzyme B₁₂, whereas that of an internal amino group is accomplished by SAM. It has been speculated that an isolated methylene radical that occurs during catalysis of lysine-5,6-aminomutase (Table 1, reaction 4), but not of lysine 2,3-aminomutase, needs to be stabilized by cob(II)alamin.³²

2.2.6 Reactivases

A remarkable feature of the eliminases and mutases is their relative stability in the presence of dioxygen. Although the coenzyme B₁₂-dependent glycerol dehydratase is also active under oxic conditions, the alternative glycyl-radical enzyme, which catalyzes the identical reaction, is rapidly cleaved at the glycyl-radical site when exposed to air. Coenzyme B₁₂-dependent enzymes have the advantage that the radical disappears by reformation of the Co–C σ -bond after each turnover. On the other hand, several coenzyme B₁₂-dependent enzymes, especially glycerol dehydratase and lysine-5,6-aminomutase, become inactivated during turnover. With glycerol as substrate, diol dehydratase from *Klebsiella oxytoca* survives only about 10⁴ turnovers, although with propane-1,2-diol its lifetime is 100 times longer.⁹¹ A chaperone-like reactivation factor has been detected, which in an ATP-dependent manner expels the inactive cob(II)alamin and replaces it by intact adenosylcobalamin.⁹² MeaB is an auxiliary protein that plays a crucial role in the assembly and protection of the coenzyme B₁₂-dependent methylmalonyl-CoA mutase. Impairments in the human homologue of MeaB, methylmalonic aciduria type A, lead to methylmalonic aciduria, an inborn error of metabolism.⁹³ Genes that probably code for related chaperones have been detected adjacent to the structural genes of glutamate mutase from *Clostridium cochlearium* (*glmL*)⁹⁴ and 2-methyleneglutarate mutase from *Eubacterium barkeri* (*mgmL*).⁹⁵

2.3 SAM Radical Enzymes

SAM radical enzymes, which generate the 5'-deoxyadenosyl radical and methionine by reductive cleavage of SAM, are often characterized by the sequence motif CX₃CX₂C, where C stands for

cysteine and X for any other of the 20 proteinogenic amino acids. Some of these enzymes contain the CX₂CX₄C motif and in one case CX₅CX₂C.⁹⁶ Amino acid sequences with these motifs have been found not only in genomes of anaerobes but also in aerobic bacteria, fungi, plants, animals, and even in humans. A bioinformatic survey published in 2002 revealed more than 600 different sequences of putative SAM radical enzymes in the database.⁹⁷ In 2008, the number already exceeded 2800¹¹ and, due to the ever increasing sequencing of genomes and metagenomes, the number will continue to rise. The number cited demonstrates the importance of SAM radical enzymes for life, but masks the fact that it comprises many enzymes that catalyze the same reaction but occur in different organisms. To date, there are about 40 different radical reactions known that are catalyzed by putative and characterized SAM radical enzymes.

All SAM radical enzymes need a low-potential one-electron donor, ferredoxin or flavodoxin (*E'* circa –500 mV), in order to reduce the [4Fe–4S]²⁺ cluster to the [4Fe–4S]¹⁺ state. Crystal structures of several SAM radical enzymes revealed that the three cysteines of the CX₃CX₂C motif coordinate three irons of the characteristic [4Fe–4S]²⁺ cluster. The fourth iron serves as binding site for SAM, which is coordinated by the amino, the carboxyl, and the sulfonium of the methionine moiety (Figure 5). On reduction of the [4Fe–4S]¹⁺ cluster, an inner shell electron transfer to the sulfonium center over a distance of 3.25 Å releases the 5'-deoxyadenosyl radical, whereby the sulfur of the methionine formed moves toward the iron by 0.63 Å.⁹⁸ Although the redox potential of trialkylsulfonium salts such as SAM has been estimated as –1.8 V, binding of SAM to the [4Fe–4S]²⁺ cluster together with the

Figure 5 Mode of SAM binding to the fourth iron of the cluster. The Fe–S distance is 3.25 Å; AdoCH₂ = 5'-deoxyadenosyl.

substrate increases the potential by at least 800 mV. There are excellent reviews on this topic.^{11,99,100}

The thus formed 5'-deoxyadenosyl radical initiates catalysis, just like its identical twin from coenzyme B₁₂, generally by hydrogen atom abstraction from the substrate, even from strong C–H bonds such as the unactivated methyl group of dethio-biotin.³ Only compound I of cytochrome P450, an iron(IV)oxo or ferryl species with an additional radical delocalized over the porphyrin and thiolate ligands, has a similar oxidizing power.¹⁰¹ The 5'-deoxyadenosine formed is either irreversibly released as product or recycled to regenerate SAM. The generation of 5'-deoxyadenosine, that is, the consumption of one SAM in every turnover, is energetically very expensive for the cell because the 5'-deoxyadenosine is degraded and SAM has to be resynthesized de novo. Hence, for ATP-forming catabolism with high turnover, the cell can only afford reversible SAM radical enzymes. Nature tends to use irreversible SAM radical enzymes for the synthesis of molecules that are only required in small number by the cell. The more extensive characterization of SAM radical enzymes, however, may uncover further examples of the reversible type.

2.3.1 Recycling SAM Radical Enzymes

The first known SAM-dependent enzyme that did not catalyze methylation, but rather a rearrangement reminiscent of a coenzyme B₁₂-dependent reaction, was lysine-2,3-aminomutase from *Clostridium* SB4, later renamed *Clostridium subterminale*. The oxygen-sensitive aminomutase, which was discovered by Barker, mediates the equilibration of (*S*)- α -lysine with (*S*)- β -lysine (Scheme 7), the first step of lysine fermentation to ammonia, acetate, and butyrate.¹⁰² Surprisingly, the catalyst of the chemically similar second step in this fermentation has been characterized as coenzyme B₁₂-dependent β -lysine-5,6-aminomutase (see above). Both

aminomutases require pyridoxal-5'-phosphate as an additional cofactor and the amino group migrations occur without exchange of the hydrogens involved with the solvent. The function of SAM in lysine-2,3-aminomutase remained an enigma for 20 years until Perry A. Frey discovered hydrogen transfer from the 5'-methylene group of SAM to α - and β -lysine.¹⁰³ This important result immediately indicated the transient formation of the 5'-deoxyadenosyl radical, which supported Barker's view of SAM being a poor man's adenosylcobalamin,⁹ although in his papers Barker never contemplated radical intermediates.

Subsequent studies in Frey's laboratory using isotopically labeled lysines were indeed able to characterize by EPR spectroscopy the postulated intermediate β -lysine-2-yl radical bound to pyridoxal-5'-phosphate via a Schiff base. But neither the 5'-deoxyadenosyl radical nor the pyridoxal-5'-phosphate adduct of the α -lysine-3-yl radical or a radical based on pyridoxal-5'-phosphate itself could be detected under these conditions. If, however, the 4-methylene group of lysine was replaced by sulfur, then the pyridoxal-5'-phosphate adduct of the 4-thia- α -lysine-3-yl radical became the major species during steady state.¹⁰ The 5'-deoxyadenosyl radical is too high in energy and therefore its concentration is too low to be observed directly by EPR. This radical was "trapped" with an alternate coenzyme, the SAM analog 3',4'-anhydroadenosylmethionine with a double bond between ribosyl-C-3' and C-4'. The resultant allylic 3',4'-anhydro-5'-deoxyadenosyl radical is spin delocalized and thus present at a much higher concentration and detectable by EPR spectroscopy.

In the initial catalytic step of lysine-2,3-aminomutase, the 3*Re*-hydrogen atom is removed from the β -carbon of α -lysine bound via the amino group to pyridoxal-5'-phosphate. The resultant 5'-deoxyadenosine acts as a spectator during the consecutive rearrangement of

Scheme 7 Reaction catalyzed by lysine-2,3-aminomutase.

the α -lysine-3-yl radical to the β -lysine-2-yl radical, probably via an aza-cyclopropylcarbinyl radical.⁴¹ Finally, the 5'-deoxyadenosine donates one methyl hydrogen back to the β -lysine-2-yl radical to form the 2*Re*-hydrogen of the product (*S*)- β -lysine, resulting in an overall inversion of configuration at both chiral centers. The regenerated 5'-deoxyadenosyl radical is either ready for the next turnover or recombines with methionine coordinated to the [4Fe-4S] cluster to regenerate SAM.

The mechanism of the coenzyme B₁₂-dependent β -lysine-5,6-aminomutase closely resembles that of lysine-2,3-aminomutase and raises the question as to why two different cofactors are required for almost identical reactions in the same organism. The only difference is the reversible conversion of an unactivated methyl group into a methylene group by β -lysine-5,6-aminomutase, whereas with α -lysine-2,3-aminomutase, an unactivated methylene group is reversibly converted into a methine group. The energy difference for the more difficult removal of a hydrogen atom from a methyl group versus removal from a methylene group⁷⁴ is about 10 kJ mol⁻¹ possibly resulting in up to a 100-fold rate difference. It was recently proposed that the intermediate methylene radical in β -lysine-5,6-aminomutase is stabilized by interaction with cob(II)alamin, whereas this is not necessary for α -lysine-2,3-aminomutase.^{32,56,104,105}

Bioinformatics has indicated the existence of many other SAM-dependent 2,3-aminomutases. The enzyme from *E. coli* acts on (*S*)- α -lysine, like that from *C. subterminale*, but the product is (*R*)- β -lysine, whereby the 3*Si*-H rather than 3*Re*-H is initially abstracted.¹⁰⁶ Expression of a gene from *Clostridium difficile* homologous to α -lysine-2,3-aminomutase and analysis of the protein indicated the production of a (*S*)-glutamate-2,3-aminomutase.¹⁰⁷ In the active site of this enzyme, asparagine 369 and lysine 332 replace the two aspartates (D293 and D330) of lysine-2,3-aminomutase that interact with the ϵ -amino group of lysine. Finally, there is a fourth enzyme of this group, arginine-2,3-aminomutase that catalyzes the reversible interconversion of (*S*)- α -arginine with (*S*)- β -arginine in *Streptomyces griseochromogenes*.¹⁰⁸

Spore photoproduct lyase, which occurs in endospore-forming bacteria such as the aerobic *Bacillus subtilis* and the anaerobe *Clostridium acetobutylicum* was long considered to be the only

recycling SAM radical enzyme other than the 2,3-aminomutases acting on amino acids. Recent experiments suggest, however, that this is not the case.¹⁰⁹ In contrast to lysine-2,3-aminomutase, which is involved in the energy metabolism of the strict anaerobe *C. subterminale* that requires a high turnover, spore photoproduct lyase has to repair DNA lesions that occasionally occur in bacteria germinated from spores. After repair, the two separated nucleotides fold back into the double helix and the enzyme moves along the DNA until it detects another lesion, which has to flip out from the helix. Hence, the organism does not need an enzyme with high turnover and can afford to spend one SAM for every DNA lesion.

As the name indicates, the spore photoproduct can only be formed by irradiation of packed dry DNA that occurs in spores. In the overall reaction, the methyl group of thymidine adds stereospecifically in a *syn*-geometry to the double bond of the neighboring thymidine to yield the dimeric (*5R*)-thymidine, probably via radical intermediates (Scheme 8). The repair mechanism is straightforward—just the reverse of the formation.^{110,111} Abstraction of the added hydrogen by the 5'-deoxyadenosyl radical derived from SAM yields a radical that fragments into thymidine and a thymidine radical. The latter is recycled by reaction with 5'-deoxyadenosine or is reduced by an unknown electron donor (Scheme 8), probably via a conserved cysteine residue.¹⁰⁹ Which of the C-6 hydrogen atoms is removed by the 5'-deoxyadenosyl radical remains to be established.

A very recently characterized reversible radical SAM enzyme is DesII that catalyzes the $\alpha\beta$ -elimination of ammonia from a 2-aminoethanol moiety in the biosynthesis of the sugar thymidine diphosphate (TDP)-D-desosamine.¹¹² In this pathway, the keto group at C-4 of TDP-6-deoxy-4-dehydro-D-glucose is converted to an amino group by pyridoxal-5'-phosphate-dependent amino transfer from glutamate. The 5'-deoxyadenosyl radical derived from SAM abstracts the hydrogen atom at C-3 causing the elimination of ammonia at C-4, possibly via a ketyl radical. The resulting product-related radical recycles SAM from 5'-deoxadenosine and methionine, leading to TDP-4,6-dideoxy-3-dehydro-D-glucose. If TDP-4-amino-4,6-dideoxy-D-[3-²H]glucose is used as substrate, after some turnovers, the 5'-methylene group of SAM contains two deuterium atoms,

Scheme 8 Radical mechanisms for formation and irreversible cleavage of the spore photoproduct. Steps A, B, and C are catalyzed by spore photoproduct lyase.

showing that SAM has been recycled. The enzyme DesII is remarkable in two ways. First, it shows how nature aided by an aminotransferase converts a keto to a methylene group adjacent to a hydroxyl group. Second, the reaction is almost identical to that mediated by the adenosylcobalamin-dependent EAL (Section 2.2.3).

2.3.2 Irreversible SAM Radical Enzymes

The large group of irreversible SAM radical enzymes comprises the activases of glycyl-radical enzymes, which together with their target enzymes deserve a separate study. Several crystal structures have been determined for these SAM radical enzymes, which pave the way to mechanistic proposals. The products of the reactions catalyzed by these enzymes are equal amounts of methionine, 5'-deoxyadenosine, and a substrate-derived radical that is converted into the product-related radical. An interesting yet unsolved question is the quenching of the latter radical. It could be removed either by oxidation or by reduction via proton-coupled electron transfers. The electron donors/acceptors could be ferredoxin or flavodoxin as required for radical formation. Many SAM radical enzymes have a second [4Fe-4S] cluster coordinated by other cysteine

residues of the protein, which could be involved in the electron transfer. The following paragraphs comprise specific SAM radical enzymes. They are grouped by their catalytic reactions and not with respect to their phylogenetic relationships.

In *glycyl-radical enzymes*, a conserved glycine (RVXG) near the C-terminus of one subunit of a large dimeric *apo*-enzyme ($2 \times \sim 80$ kDa) is irreversibly converted to a carbon-based radical through stereospecific α -hydrogen atom abstraction effected by the 5'-deoxyadenosyl radical derived from SAM. As discovered with pyruvate formate lyase, the relatively stable glycyl radical exhibits a characteristic EPR signal, resulting from coupling with the hydrogen that remains on the amino acid.^{113,114} Quantum mechanical calculations demonstrated that glycine gives the thermodynamically most stable radical as compared to the other proteinogenic amino acids (see **Radical Stability—Thermochemical Aspects**).¹¹⁵ The facile reaction of the radical with molecular oxygen inactivates the enzyme by cleavage of the polypeptide chain at the glycine residue. Hence, these enzymes can occur only in microorganisms that thrive anaerobically.

The structure of pyruvate formate lyase revealed an $(\alpha\beta)_{10}$ barrel. At the center of the barrel, the glycyl radical is located like the rotating knife of a Waring Blender.¹¹⁶ This architecture prevents the radical

from dimerizing and allows catalysis without side reactions.¹¹⁷ The 5'-deoxyadenosyl radical is generated by the action of the SAM-dependent pyruvate formate lyase activating enzyme, which contains the specific [4Fe-4S] cluster. The C-terminal domain with the glycine residue is turned inside out, thereby reaching the active site of the activating enzyme. Afterwards, the glycine radical domain flips back into the center of the lyase and catalysis can start.¹¹⁸ On addition of pyruvate, the radical is transferred to a cysteine residue, which is conserved in all glycine radical enzymes. Only in pyruvate formate lyase does the radical move to an adjacent cysteine that is specific for this type of enzyme. It has been proposed that the thiyl radical thus formed adds to the carbonyl group of pyruvate and the resulting adduct fragments into *S*-acetylcysteine and a formyl radical anion. The conserved cysteine residue donates a hydrogen atom to the formyl species yielding formate, while the thiyl radical is recycled. Finally, the acetyl moiety is transferred from cysteine-SH to CoASH.¹¹⁹

$$\Delta G^{\circ} = -16 \text{ kJ mol}^{-1}$$

The calculated free energy indicates that this reaction is reversible, though the equilibrium lies almost completely on the right side. In the direction of pyruvate synthesis, the thiyl radical has to abstract the hydrogen atom from formate, which is feasible because the resulting radical anion is spin delocalized.

There are only six additional glycy radical enzymes known¹²⁰:

- The anaerobic or type III RNR,^{121,122} which is discussed in Section 2.1.
- 2-Oxobutyrate formate lyase, which is closely related to pyruvate formate lyase.¹²³
- Benzylsuccinate synthase, see Scheme 9a^{124–130}; a similar enzyme catalyzes the addition of fumarate to *m*-xylene.¹²⁹
- Presumably 2-(1-methylpentyl)succinate synthase, see Scheme 9b.¹³¹
- *p*-Hydroxyphenylacetate decarboxylase, see Scheme 10.^{132–134}
- Glycerol dehydratase. The functionally similar coenzyme B₁₂-dependent enzyme^{135,136} is discussed in Section 2.2.3.

The glycy radical enzymes benzylsuccinate synthase and 2-(1-methylpentyl)succinate synthase catalyze the addition of fumarate to the hydrocarbons toluene and hexane, respectively (Scheme 9). In this way, the hydrocarbon is converted into a water-soluble product that can be thioesterified with CoASH for the subsequent β -oxidation. The initial step in fumarate addition most likely proceeds via radicals derived from the hydrocarbons. Although the benzyl radical derived from toluene is spin delocalized, the only stabilization of the hex-2-yl radical is by hyperconjugation. Evidently, the thiyl radical of the enzyme abstracts a hydrogen atom from C-2 (calculated difference in bond dissociation energy, $\Delta\text{BDE} \approx 40 \text{ kJ mol}^{-1}$) rather than from C-1 of hexane ($\Delta\text{BDE} \approx 50 \text{ kJ mol}^{-1}$).⁷⁴ It is still difficult to understand how the thiyl radical can manage the energy difference of 40 kJ mol^{-1} . Furthermore, sulfate-reducing bacteria have recently been described that are able to degrade propane by addition of fumarate even to the methyl

Scheme 9 Initial steps of hydrocarbon degradation by addition to fumarate catalyzed by glycy radical enzymes: (a) degradation of toluene and (b) degradation of hexane.

Scheme 10 Proposed Kolbe-type mechanism for the decarboxylation of *p*-hydroxyphenylacetate catalyzed by a glycyl-radical enzyme.

group as well as to the methylene.¹³⁷ There is, however, a remarkable difference within benzylsuccinate synthase and 2-(1-methylpentyl)succinate synthase. Using dideuterofumarate, the succinate moiety of benzylsuccinate retained both deuteriums (H. Wilkes, R. Rabus, J. Heider, and F. Widdel, personal communication), whereas in 2-(1-methylpentyl)succinate, the deuterium at the tertiary carbon was lost.¹³¹ Possibly this difference is caused by an epimerase, because the subsequent carbon-skeleton rearrangement of 2-(1-methylpentyl)succinyl-CoA to the malonyl-CoA derivative, 2-carboxy-4-methyloctanoyl-CoA,¹³¹ could require a different stereoconfiguration.

Direct decarboxylation of *p*-hydroxyphenylacetate would lead to a destabilized carbanion because of the electron-rich phenolic substituent. However, abstraction of the phenolic hydrogen atom by the thiyl radical of the enzyme would generate a stabilized phenoxyl radical that can decarboxylate due to the spin delocalized *p*-cresoyl radical anion that is formed.¹³² Interestingly, the fragmentation of tyrosine to dehydroglycine catalyzed by the SAM radical enzyme ThiH most likely leads to the same *p*-cresoyl radical anion (Scheme 11). Owing to the facile formation and stability of this radical, nature destroys a whole tyrosine molecule just to secure either CO and HCN for the maturation of the [FeFe]hydrogenase or a C=N unit for the synthesis of the thiazole ring of thiamin diphosphate (ThDP). Surprisingly, the crystal structure of the unactivated *p*-hydroxyphenylacetate decarboxylase with bound substrate revealed that the cysteine

converted to the catalytic thiyl radical is located close to the carboxyl moiety rather than near the phenolic hydroxyl group.^{138,139} As all structurally characterized unactivated glycyl-radical enzymes contain the substrate in the correct orientation, an alternative Kolbe-type mechanism has been proposed. Oxidation of the carboxylate by the nearby thiyl radical and deprotonation of the phenolic hydrogen by a glutamate residue triggers decarboxylation and the formation of the *p*-cresoyl radical anion (Scheme 10). ThiH, however, has no choice. In this reaction, the phenolic hydrogen has to be abstracted by the 5'-deoxyadenosyl radical.

The pathogenic anaerobic bacterium *C. difficile* produces *p*-cresol from tyrosine probably to suppress other bacteria in the human intestine. The decarboxylase is an octamer composed of four large subunits (4×100 kDa) that contain the active site glycine and cysteine as well as four small subunits (4×9.5 kDa), each of which comprises two [4Fe-4S] clusters. Probably, the clusters, which are essential for activity, reduce the glycyl radical to glycine to avoid suicide of the bacterium if the concentration of cresol rises to toxic values.^{133,134}

The activating SAM radical enzymes of *p*-hydroxyphenylacetate decarboxylase, glycerol dehydratase, and benzylsuccinate synthase contain two additional [4Fe-4S] clusters with unknown functions. This makes them distinct from the activases of pyruvate formate lyase and RNR, in which only the typical SAM cluster is present. While the 5'-deoxyadenosyl radical forms the glycyl-radical in *p*-hydroxyphenylacetate decarboxylase,¹³⁹ the activase of glycerol dehydratase appears to cleave SAM into 5'-methylthioadenosine and the

Scheme 11 Generation of dehydroglycine from tyrosine catalyzed by HydG leading to hydrogenase or by ThiH leading to thiamin diphosphate. If no acceptor is present, dehydroglycine hydrolyzes to glyoxylate.

2-aminobutyryl-4-yl radical that abstracts the hydrogen from a specific glycine residue.¹⁴⁰ The same fragmentation of SAM also occurs in the synthesis of wybutosine and diphthamide (Figure 7).

Activation of Sulfatases by Oxidation of an Alcohol to an Aldehyde

In biology, the most common electron acceptor for the oxidation of alcohols to aldehydes ($E^{\circ'} = -300 - 0 \text{ mV}$ against the hydrogen electrode at pH 7.0) is NAD^+ ($E^{\circ'} = -320 \text{ mV}$; under physiological conditions $E' = -270 \text{ mV}$). Therefore, in most cases, the equilibria for these oxidations lie on the side of the alcohol. To achieve complete oxidation of an alcohol to an aldehyde, aerobes employ the very strong oxidant molecular oxygen ($E^{\circ'} = +820 \text{ mV}$), whereas anaerobes use the 5'-deoxyadenosyl radical derived from SAM. This was shown for the maturation of the sulfatase AtsA by AtsB of *Klebsiella pneumoniae*¹⁴¹ and for the anaerobic sulfatase maturing enzyme (an SME) from *Clostridium perfringens*.¹⁴² In both of the enzymes, a specific serine or a cysteine residue is oxidized with one 5'-deoxyadenosyl radical to a 3-oxoalanine (formylglycine) residue. The reaction

probably proceeds via a ketyl or thioketyl radical, which after deprotonation at the oxygen or sulfur is further oxidized to the aldehyde or thioaldehyde. The latter is hydrolyzed to an aldehyde. The maturase contains two additional [4Fe-4S] clusters, which are probably involved in the electron transfer. In the sulfatase mechanism, the sulfate is transferred to the hydrated aldehyde, which expels the sulfate with regeneration of the aldehyde.

Fragmentations and Rearrangements by SAM Radical Enzymes

Coproporphyrinogen III oxidase from *E. coli* catalyzes the oxidative decarboxylation of two propionate side chains of coproporphyrinogen to vinyl side chains.¹⁴³ The 5'-deoxyadenosyl radical abstracts the β -Si-hydrogen of a propionate residue to generate a spin delocalized radical, which has been observed.¹⁴⁴ Decarboxylation of this fairly stable radical is probably initiated by an unknown electron acceptor. The second vinyl group is presumably formed in the same way, as the crystal structure shows two SAM molecules.¹⁴⁵

Figure 6 Examples of sulfur insertion by radical SAM enzymes.

Figure 7 Modifications of 23S rRNA, tRNA, and elongation factor 2. The red carbons stem from SAM by N-, O-, or C-methylation; the pink structures originate from SAM by alternate cleavage. Acetyl-CoA is the most likely precursor of the blue moieties. R = 1-ribosyl.

The extremely active [FeFe]hydrogenases catalyze the reduction of protons to molecular hydrogen by reduced ferredoxin or flavodoxin, whereas the less active [Fe]hydrogenases (see below) and [NiFe]hydrogenases are primarily involved in the uptake of hydrogen due to the higher redox potentials of their electron acceptors. [FeFe]hydrogenase comprises a [4Fe–4S] cluster connected via a cysteine to a two-iron active site that is bridged by a dithiolate ($\text{HS-CH}_2\text{-X-CH}_2\text{-SH}$; X = probably NH) and coordinated by three CO and two CN^- . Three enzymes, HydE, HydF, and HydG, are required for maturation of the hydrogenase. The radical SAM enzyme HydG probably catalyzes the abstraction of the phenolic hydrogen from tyrosine.^{146,147} The resulting tyrosyl radical fragments to the resonance stabilized *p*-cresoyl radical anion and dehydroglycine, which disintegrates into CO, HCN, and H_2O (Scheme 11). HydE is most likely involved in the radical SAM-dependent synthesis of the dithiolate cofactor and the whole active site of the hydrogenase is assembled on the scaffold HydF accompanied by guanosine triphosphate (GTP) hydrolysis.

An enzyme related to HydG is ThiH, which is responsible for the biosynthesis of the thiazole ring of ThDP, the physiological active form of vitamin B₁. ThDP is the cofactor for the metabolism of ketosugars and 2-oxoacids, for example, pyruvate. Like HydG, ThiH catalyzes the cleavage of tyrosine to the *p*-cresoyl radical and dehydroglycine, which acts as a building block of the thiazole ring. If dehydroglycine is not used for the consecutive step, it spontaneously hydrolyzes to ammonia and glyoxylate, which were identified (Scheme 11).¹⁴⁸ The reduction and protonation of the *p*-cresoyl

radical to *p*-cresol remains to be established. Interestingly, the dehydroglycine used by aerobic organisms for thiamin biosynthesis is obtained from glycine with oxygen as oxidant. Hence, the 5'-deoxyadenosyl radical derived from SAM can be regarded as “the oxygen of the anaerobes.”

Molybdopterin is the cofactor of many oxidases, for example, xanthine oxidase in mammalian milk. Its biosynthesis in *Staphylococcus aureus*¹⁴⁹ and most likely in all kingdoms of life including humans is catalyzed by MoaA and the accessory protein MoaC. The pathway starts with the fragmentation of the ribose C-2'–C-3' bond of GTP, followed by insertion of the C-8 methine group of the guanine ring (Scheme 12).¹⁵⁰ The enzyme contains, in addition to the N-terminal “SAM cluster,” a second C-terminal [4Fe–4S] cluster that binds GTP at the two imidazole nitrogens. The 5'-deoxyadenosyl radical abstracts a hydrogen atom either from C-2' or C-3' of the ribose. The product is called *precursor Z*, an oxygen-sensitive tetrahydropyranopterin that is further converted to the mature cofactor molybdopterin.

An even more complex fragmentation and rearrangement is the “radical dance” catalyzed by the single enzyme ThiC from the bacterium *Caulobacter crescentus*. Induced by one electron, it converts SAM and aminoimidazole ribonucleotide (AIR), an intermediate in the purine nucleotide biosynthesis pathway, to 5'-deoxyadenosine, CO, formate, and hydroxymethylpyrimidine phosphate, the other building block of ThDP (Scheme 13).¹⁵¹ Amazingly, only one SAM molecule is required for each turnover but it is used twice, as revealed by the incorporation of two deuterium atoms from the substrate into the 5-methyl group of 5'-deoxyadenosine,

Scheme 12 Radical SAM-dependent initial step in the biosynthesis of molybdopterin.

Scheme 13 Synthesis of the hydroxymethylpyrimidine phosphate (HMP-P) building block of thiamin diphosphate from 5-aminoimidazole nucleotide (AIR) catalyzed by the SAM radical enzyme ThiC. One red hydrogen and the bold black hydrogen of AIR end up in the 5'-methylene group of 5'-deoxyadenosine. The two bold black hydrogens in HMP-P come from the solvent water.

one from the 5'-carbon and the other from the 4'-carbon of AIR. The authors suggested that after the first H-abstraction, SAM is recycled, but it is then used irreversibly for the second abstraction. On incubation of ThiC with SAM and a reducing agent, a protein-based radical was also observed.¹⁵² Whether this radical is catalytically competent remains to be established.

The structure of ThiC also yielded surprises. Each subunit of the homodimeric enzyme is composed of a $(\beta\alpha)_8$ barrel with an extra domain, which contains the [4Fe-4S] cluster coordinated to a CX₂CX₄C motif.¹⁵³ The enzyme with the closest architecture is glutamate mutase from *C. cochlearium* (see above), which is composed of a $(\beta\alpha)_8$ barrel-containing

GlmE homodimer and to each subunit the coenzyme B₁₂-binding subunit GlmS is attached. Hence, in both the enzymes, the “radical reaction flask” is similar with only the radical-generating domains or subunits being different. The same situation is found in the three classes of RNRs (see above).

Very recently, yet another intriguing rearrangement was revealed. The SAM radical enzyme NosL from *Streptomyces actuosus* catalyzes the fragmentation of tryptophan and its recombination to 3-methyl-2-indolic acid, a building block of the antibiotic thiopeptide nosiheptide. Completely deuterated tryptophan only lost the deuterium at C-2 and the 5'-deoxyadenosine formed was not labeled. Hence, the fragmentation was most likely induced

Scheme 14 Synthesis of pyrrolysine, the 22nd proteinogenic amino acid.

by abstraction of the imino hydrogen that resulted in the removal of the glycyI moiety and recombination with the carboxylate, whereas the glycyI α -carbon was converted to ammonia and CO.¹⁵⁴

A reaction that closely resembles the carbon-skeleton rearrangement catalyzed by the coenzyme B₁₂-dependent glutamate mutase (Scheme 6) is involved in the biosynthesis of the 22nd proteinogenic amino acid pyrrolysine (Scheme 14). Archaeal methyltransferases contain in their amino acid sequence a specific L-lysine, to whose ϵ -amino group a methylated pyrroline carboxylate is attached via an amide linkage. The pyrroline is derived by oxidation of (2R,3R)-3-methylornithine, which is obtained from L-lysine by a carbon-skeleton rearrangement catalyzed by the SAM radical enzyme PylB.¹⁵⁵ The difference from the reaction catalyzed by the reversible glutamate mutase is inversion of configuration at the amino carbon and the irreversibility due to the consumption of most likely one SAM per turnover. One can assume that the 5'-deoxyadenosyl radical abstracts a hydrogen atom from C-4 of lysine and the resulting 4-lysyl radical fragments to a glycyI-radical and 4-amino-1-butene. Recombination by addition of the glycyI-radical at C-2 of 4-amino-1-butene, followed by one-electron reduction and protonation, would yield the branched carbon chain of (2R,3R)-3-methylornithine. An alternative pathway, in which the fragmentation occurs between C-4 and C-5,¹⁵⁶ appears very unlikely because the resulting 2-aminoethyl radical is not as stabilized as the glycyI radical.

Sulfur Insertion by SAM Radical Enzymes

The common theme of this topic is the abstraction of a hydrogen atom bound to carbon, followed by insertion of sulfur derived from a second iron-sulfur cluster of the SAM radical enzyme; for a review see Ref. 157. The most prominent enzyme of this group is biotin synthase from

E. coli. This enzyme catalyzes the formation a sulfur bridge between a methyl and a methylene group of its substrate dethiobiotin at the expense of two molecules of SAM, which are both converted to 5'-deoxyadenosine. The enzyme contains the standard radical SAM [4Fe-4S] cluster and an additional [2Fe-2S] cluster,¹⁵⁸ which donates the sulfur.³ Hence, the enzyme sacrifices itself during the turnover. But even in the presence of a sulfur source that regenerates the cluster, no more than one turnover could be observed. Recently, it has been shown that impurities and degradation products of SAM, especially adenosylhomocysteine (SAM without the methyl group) strongly inhibited the reaction. Using enzymatically synthesized pure SAM under strictly anaerobic conditions, many turnovers could be observed.¹⁵⁹ After its synthesis, biotin is attached to a specific lysine residue of an *apo*-carboxylase, in a reaction catalyzed by the ATP-dependent biotin ligase.

The synthesis of the lysine-bound lipoyl residues in 2-oxoacid-dehydrogenases occurs in a different order. First, octanoic acid is attached to a conserved lysine residue of the protein, and second, one sulfur atom is inserted at C-6 followed by the other sulfur at C-8, both catalyzed by LipA. Like biotin synthase, the whole process requires two molecules of SAM, and the sulfur originates from the additional [4Fe-4S] cluster.¹⁶⁰

The syntheses of thiomethyl groups by the radical SAM enzymes RimO from *T. maritima*, as well as MtaB and MiaB from *B. subtilis*, follow a similar scheme: hydrogen atom abstraction, sulfur insertion, and final methylation by a second SAM. RimO catalyzes methylthiolation at the methylene group of a specific aspartate residue in the S12 ribosomal protein.¹⁶¹ MtaB and MiaB are responsible for the final maturation of tRNA at already modified bases near the anticodon. They catalyze the introduction of thiomethyl groups into position 2 of *N*⁶-threonylcarbamoyladenosine and

*N*⁶-isopentenyladenosine.¹⁶² All three thiomethyl residues are essential for protein biosynthesis. A variant within the human gene CDKAL1 belonging to the eukaryotic MtaB subfamily is unable to catalyze thiomethylation, a genetic defect shown to predispose for type 2 diabetes.¹⁶³

C–C Bond Formation by SAM Radical Enzymes

The methyltransferases RlmN and Cfr catalyze methyl transfer to aromatic carbon atoms of an adenosine within a complex 23 S rRNA substrate to form the 2,8-dimethylated product.¹⁶⁴ The introduction of one methyl group requires two SAM molecules: one for radical formation and the second as methyl donor. In this way, the 5'-deoxyadenosyl radical derived from one SAM abstracts a *hydrogen atom from the methyl group* of the second SAM. This new radical adds to the adenosine carbon to be methylated. One-electron reduction and a hydride shift result in the formation of the methylated product and adenosylhomocysteine, in addition to methionine and 5'-deoxyadenosine.¹⁶⁵ A consecutive paper shows, however, that the second SAM methylates a conserved cysteine residue of the enzyme. The 5'-deoxyadenosyl radical then abstracts a hydrogen atom from this methyl group to afford a methylene radical that adds to the purine ring. In contrast to the hydride shift, the authors propose deprotonation/protonation steps and cleavage of the S–C bond by disulfide formation.¹⁶⁶

Recently, one enzyme has been discovered that cleaves SAM in a different manner to methyladenosine and a 3-amino-3-carboxypropyl radical.¹⁶⁷ The enzyme is involved in diphthamide biosynthesis in Archaea and Eukarya. The 3-amino-3-carboxypropyl radical adds at the carbon between the two imidazole nitrogens of a specific histidine residue of the elongation factor 2 required for protein biosynthesis. The crystal structure of the enzyme from *Pyrococcus horikoshii* revealed an [4Fe–4S] cluster coordinated by three cysteine residues, which do not show the CX₃CX₂C motif but are spread over the whole molecule. The adduct is further modified by three SAM-dependent methylations at the amino group and conversion of the carboxylate to an amide. Diphtheria toxin catalyzes the NAD⁺-dependent ADP ribosylation at N–H of the imidazole moiety, which arrests protein synthesis.

The combination of three different SAM-dependent C–C bond forming reactions

is found in the biosynthesis of wyosine derivatives: SAM-dependent addition of a C-2 unit, probably an acetyl group, to *N*¹-methylguanosine to yield the tricyclic 4-demethylwyosine. This is followed by C-methylation at C-6 and addition of the 3-amino-3-carboxypropyl radical derived from SAM at C-7. Finally, conversion to the methyl ester and N-acetylation leads to wybutosine in archaeal and eucaryal tRNAs.¹⁶⁸

Unknown Reactions Catalyzed by the SAM Radical Enzymes NirJ, BchE, PqqE, HmdB (HcgA), NifB, and Viperin

NirJ is involved in the transformation of precorrin-2 into heme *d*₁, a cofactor of nitrite reductase also called cytochrome *cd*₁.¹⁶⁹ It was suggested that NirJ catalyzes the replacement of two propionate side chains by keto groups. The authors claimed to have detected the 5'-deoxyadenosyl radical by EPR merely on incubation of NirJ from *Paracoccus pantotrophus* with SAM and dithionite.

Under anaerobic conditions, BchE catalyzes the formation of the isocyclic ring of protochlorophyllide from magnesium-protoporphyrin monomethyl ester in the phototrophic bacterium *Rhodobacter capsulatus*, a step in bacteriochlorophyll biosynthesis. Surprisingly, the enzyme requires adenosylcobalamin besides SAM.¹⁷⁰ The reaction comprises the oxidation of a methylene group to a ketone and the removal of two hydrogen atoms for cyclization. Under aerobic conditions, the same reaction uses dioxygen (Scheme 15).

PqqE from *K. pneumoniae* catalyzes an early step in the formation of protein-bound pyrroloquinoline quinone (PQQ, Figure 8a) by condensation of a glutamate and a tyrosine side chain in the protein PpqD.¹⁷¹ Surprisingly, consecutive steps require molecular oxygen for hydroxylation reactions. PQQ is an oxidant with a more positive redox potential than NAD⁺. It is involved in, for example, the aerobic oxidation of ethanol in wine to acetic acid during vinegar production in *Acetobacter* species.

HmdB also named HcgA, is involved in the synthesis of the prosthetic group of the so-called [Fe]hydrogenase (HmdA) occurring in methanogenic Archaea (Figure 8). HmdA catalyzes the reduction of methenyl-tetrahydromethanopterin to methylene-tetrahydromethanopterin by molecular hydrogen. Biochemical characterization of the enzyme has revealed the presence of a unique active site metal cofactor, which consists of an

Scheme 15 Formation of the isocyclic ring in protochlorophyllide.

Figure 8 PQQ is formed by condensation of a glutamyl and a tyrosyl residue in a peptide. In [Fe]hydrogenase, the hydrogen probably binds to the open sixth coordination site of Fe. GMP, guanosine monophosphate.

iron ion ligated by two CO molecules, a cysteine side chain, a guanylyl pyridinol cofactor, and an unknown ligand suggested from crystallographic data to be the acyl side chain from the pyridinol (Figure 8b).¹⁷² Recently, it has been elucidated that HmdB is a radical SAM enzyme despite its unusual CX₅CX₂C motif.⁹⁶ HmdB could be involved in the formation of CO like HydG or ThiC as shown above or more likely in C-methylation of the pyridinol. It has been shown that one of the two methyl groups stems from methionine.¹⁷²

NifB is required for the biosynthesis of the MoFe cofactor of nitrogenase that catalyzes the reduction of dinitrogen to ammonia.^{173,174} NifB probably bridges two [4Fe–4S] clusters by inserting a sulfur atom along with the central atom, X = C, N, or O, thereby generating a FeS scaffold that is rearranged into a precursor, closely resembling the

core structure of the mature FeMoCo. Afterwards, Mo and homocitrate are added.

The interferon-induced antiviral protein viperin is a radical SAM enzyme that inhibits influenza A virus release from the plasma membrane of infected cells.¹⁷⁵ Viperin probably interacts with farnesyl diphosphate synthase, which affects the membrane fluidity.¹⁷⁶

2.4 Reactions Involving Ketyl Radicals

One-electron reduction of carbonyl groups, in ketones, thioesters, or amides, generates nucleophilic ketyl radicals. The extra electron is located in the 2p_z antibonding orbital of the carbonyl group and is stabilized by the electronegative oxygen atom.¹⁷⁷ The “Umpolung” or polarity inversion¹⁷⁸ of carbonyl groups in this way gives versatile intermediates with remarkable properties.⁵⁴ The nucleophilic character of ketyl radicals can be denoted by placing their negative charge at the carbon, which triggers elimination of an adjacent leaving group such as hydroxyl. This provides a useful method in synthetic chemistry for preparing ketones from α -hydroxyketones using one-electron donors such as Zn(0), Cr(II), and Sm(II) (see **Organic Synthesis Using Samarium Diiodide**). This reaction is thought to proceed via a ketyl radical that eliminates the hydroxyl to give an enoxy radical, which suffers one-electron reduction and protonation to yield the ketone.^{82b}

2.4.1 2-Hydroxyacyl-CoA Dehydratases

Several clostridia and fusobacteria thrive on the fermentation of amino acids to ammonia, CO₂, acetate, short-chain fatty acids, and H₂. Some of these fermentations occur pairwise, one amino acid acting as electron donor and the other as acceptor. These dismutations are called *Stickland reactions*,¹⁷⁹ but single amino acids such as alanine and leucine can disproportionate in a similar manner.³⁹ The acidic and basic amino acids are degraded by special pathways, in which radical enzymes are involved that have been described above, such as the SAM-dependent lysine-2,3-aminomutase and the coenzyme B₁₂-dependent enzymes methylmalonyl-CoA mutase (for aspartate), glutamate mutase, β -lysine-5,6-aminomutase, and ornithine-4,5-aminomutase (for arginine). Although the oxidative fermentation branches apparently resemble amino acid oxidations in aerobes, the irreversible NAD-dependent 2-oxoacid dehydrogenases are replaced by reversible 2-oxoacid ferredoxin oxidoreductases that comprise relatively stable radical intermediates in their catalytic pathways (see below). The reductions of 12 of the 20 proteinogenic amino acids to short-chain fatty acids are unique and exhibit a different type of radical chemistry. They proceed via their conversion to the corresponding (*R*)-2-hydroxy acids. This is followed by activation to (*R*)-2-hydroxyacyl-CoA, dehydration

to enoyl-CoA, reduction to saturated acyl-CoA, and excretion of the free fatty acid.^{54, 180–182}

The most interesting enzyme in this pathway is 2-hydroxyacyl-CoA dehydratase, whose substrate encounters the same problem as the parent amino acid, the activation of the β -hydrogen atom with a $pK_a \approx 40$. The reason for the conversion of the amino acids to the 2-hydroxy acids could be twofold. First, owing to their quite negative free energy change for hydrolysis, CoA-thioesters of α -amino acids are very unstable and tend to polymerize. In biology, the only known thioesters of α -amino acids are covalently bound to nonribosomal peptide synthetases, where polymerization is inhibited by structural separation.¹⁸³ Second, the elimination of a hydroxyl group adjacent to the electron withdrawing thioester via ketyl radicals may be easier than that of an amino group as demonstrated in the mechanistic proposal (Scheme 16).

This mechanism starts with a high-energy electron (E' circa -900 mV) that reduces the thioester carbonyl to a ketyl radical, which eliminates the adjacent hydroxyl group.⁸² It has been calculated that the pK_a of the β -proton of the resulting enoxy radical is 26 units lower as compared to that of the substrate.¹⁸⁴ After deprotonation, the allylic ketyl radical formed recycles its extra electron back to the enzyme and the product enoyl-CoA is released (Scheme 16). To date, four such unusual enzymes have been characterized which catalyze the following dehydrations.

Scheme 16 Proposed mechanism of 2-hydroxyacyl-CoA dehydratases. R = H, methyl, acetate, propionate, propyl, isopropyl, phenyl, *p*-hydroxyphenyl, or indolyl.

Lactyl-CoA dehydratase from *Clostridium pionicum* (Scheme 16, R = H) participates in the fermentation of α - and β -alanine, serine, cysteine, threonine, and methionine and catalyzes the *syn*-dehydration of (*R*)-lactyl-CoA to acryloyl-CoA ($K_{eq} = 0.02$) and of (*R*)-2-hydroxybutyryl-CoA to (*E*)-crotonyl-CoA.^{185–188}

2-Hydroxyglutaryl-CoA dehydratases from *Acidaminococcus fermentans* and *Clostridium symbiosum* (Scheme 16, R = CH₂-COO[−]) are involved in the fermentation of glutamate, glutamine, and histidine and catalyze the *syn*-dehydration of (*R*)-hydroxyglutaryl-CoA to (*E*)-glutaconyl-CoA ($K_{eq} = 57$).^{187,189–191}

2-Hydroxyisocaproyl-CoA dehydratase from *C. difficile* (Scheme 16, R = isopropyl) is required for the fermentation of leucine and catalyzes the dehydration of (*R*)-2-hydroxyisocaproyl-CoA to isocaprenoyl-CoA (4-methylhex-2-enoyl-CoA), most likely in a *syn*-geometry to yield the *E*-isomer ($K_{eq} = 1600$).^{187,192,193}

Phenyllactyl-CoA dehydratase from *Clostridium sporogenes* (Scheme 16, R = phenyl) is implicated in the fermentation of phenylalanine, tyrosine, and tryptophan and catalyzes the *syn*-dehydration of (*R*)-phenyllactyl-CoA to (*E*)-cinnamoyl-CoA [(*E*)-phenylacryloyl-CoA],^{194,195} of (*R*)-*p*-hydroxyphenyllactyl-CoA to *p*-hydroxycinnamoyl-CoA, and of (*R*)-3-indolelactyl-CoA to (*E*)-indoleacryloyl-CoA (H. Li, A. Parthasarathy, and W. Buckel, unpublished data).

All these dehydratases consist of two extremely oxygen-sensitive proteins: a homodimeric activator or “archer”¹⁹⁶ containing one [4Fe-4S] cluster between the two subunits and the actual heterodimeric dehydratase with two [4Fe-4S] clusters, one in each subunit.^{182,197,198} The crystal structure of the activator protein of 2-hydroxyglutaryl-CoA dehydratase from *A. fermentans* revealed that helix 5 of each subunit points with its N-terminus toward the cluster, thereby forming a helix–cluster–helix architecture with an angle of 105°. ¹⁹⁹ Four cysteine residues, two from each subunit, coordinate the [4Fe-4S]²⁺ cluster, which is easily and reversibly reduced to [4Fe-4S]⁺ by ferredoxin or flavodoxin. Each of the two subunits contains one ADP occupying the ATP-binding site with an acetate and sugar kinases/heat shock protein 70/actin (ASKHA) motif.²⁰⁰ A similar structure around a [4Fe-4S]²⁺ cluster comprises the iron protein of nitrogenase, though the helix–cluster–helix

angle is wider by 45° and the ATP binds at a “Walker motif.”²⁰¹ The FeMoCo protein and the iron protein of nitrogenase form a complex that can be stabilized by ADP-AlF₄[−], a transition state analog of ATP hydrolysis. Interestingly, the structure of the complex revealed an opening of the helix–cluster–helix angle to 180°. ²⁰² With 2-hydroxyisocaproyl-CoA dehydratase and its activator from *C. difficile*, a similar complex was formed in the presence of ATP-AlF₄[−]. Accordingly, it was suggested that in the 2-hydroxyacyl-CoA dehydratases, the helix–cluster–helix angle also opens to approximately 180°, which enables docking and electron transfer to the dehydratase.²⁰³

EPR spectroscopy demonstrated ATP-dependent reduction of 2-hydroxyisocaproyl-CoA dehydratase by one electron from the reduced activator [4Fe-4S]¹⁺ cluster and the subsequent handover of the electron to the substrate. The radical species detected by EPR spectroscopy has been characterized as the most stable radical of the cycle, the product-related allylic ketyl radical (Scheme 16). The radical couples with the single protons at the γ - and δ -carbons but only weakly at the β -carbon, which was elucidated by deuterium substitution.¹⁹³

The crystal structure of 2-hydroxyisocaproyl-CoA dehydratase revealed two [4Fe-4S]²⁺ clusters, one in each subunit, at a distance of 12 Å. Each cluster is coordinated by three cysteines. In the somewhat larger α -cluster (in the α -subunit, 408 amino acid residues), a hydroxyl group is attached to the fourth iron, whereas in the β -cluster (in the β -subunit, 375 residues), the higher electron density at the corresponding iron is consistent with a hydrosulfide ligand (HS[−]), which was never detected in any cluster before. The structure with the substrate demonstrated a binding of the thioester carbonyl to the special iron of the α -cluster replacing the hydroxyl. In addition, glutamate α -55 is located at hydrogen-bonding distance to the carbonyl. Now the mechanism of the dehydration can be presented in more detail (Scheme 17).¹⁹⁸

Inside the actively growing anaerobic bacterial cell, ferredoxin occurs mainly in the reduced form and the ATP/ADP ratio is high, which keeps the activator loaded with one electron and ATP. This opens the helix–cluster–helix angle, making the activator cluster ready to interact with the dehydratase and to introduce the electron into the β -cluster. This process replicates the action of archers using ATP in their muscles to shoot

Scheme 17 Detailed mechanism of 2-hydroxyisocaproyl-CoA dehydratase (glutamate $\alpha 55$ transfers the proton shown).

an arrow. Hence, the activator has also been termed *archer*.¹⁹⁶ The extra electron of the dehydratase can be seen by EPR via the reduced β -cluster. Binding of the substrate to the α -cluster probably increases the redox potential that enables the electron to traverse the distance of 12 Å from the β - to the α -cluster, where it reduces the substrate to the ketyl radical via inner shell electron transfer. The ketyl radical formed binds more weakly to the cluster than the thioester carbonyl and is replaced by the hydroxyl group of the substrate, a process called *ligand swapping*. The proton is taken up by glutamate $\alpha 55$. The ketyl radical eliminates $^-\text{O}-\text{Fe}$, which acts as a base to remove the β -proton consistent with the observed *syn*-geometry. Glutamate $\alpha 55$ protonates $\text{HO}-\text{Fe}$ to give water and the allylic ketyl radical recycles the electron back to the cluster. The product isocaprenoyl-CoA leaves the enzyme and the open Fe site of the cluster binds either the next substrate

or water, which is deprotonated by glutamate $\alpha 55$ (Scheme 17).

Although Scheme 17 appears complicated, the use of just one electron provides an explanation as to how an “impossible” dehydration can occur. “Impossible” means that a standard E2 elimination cannot work, because the β -hydrogens have a pK_a that is too high. Ultimately, the electron is recycled back to the enzyme, ready for the next turnover and is used about 10 000 times until a new activation is required. The need to regenerate the electron is because of its dissipation by a second electron transfer, either to the substrate or to an external oxidant.¹⁹²

Hence, 2-hydroxyacyl-CoA dehydratases demonstrate a new mode of radical formation in biology, which proceeds without the use of complex cofactors such as coenzyme B_{12} or SAM. The α -cluster in the 2-hydroxyacyl-CoA dehydratases has a dual function, namely electron transfer and Lewis acid

catalysis to facilitate elimination. This function resembles the SAM radical enzymes by coordination of SAM to the fourth iron of the cluster and electron transfer to generate the 5'-deoxyadenosyl radical. The three cysteines of both dehydratase clusters, however, are not part of a consensus sequence but are spread over the whole polypeptide chains.¹⁹⁸

2.4.2 4-Hydroxybutyryl-CoA Dehydratase

Decarboxylation of glutamate yields 4-aminobutyrate (γ -aminobutyric acid, gamma-aminobutyric acid (GABA)) that is fermented by *Clostridium aminobutyricum* to ammonia, acetate, and butyrate. The pathway proceeds via succinic semialdehyde, 4-hydroxybutyrate, and 4-hydroxybutyryl-CoA that is dehydrated to crotonyl-CoA [(*E*)-but-2-enoyl-CoA]. Crotonyl-CoA disproportionates oxidatively to acetate and reductively to butyrate. The key enzyme of this pathway is 4-hydroxybutyryl-CoA dehydratase that catalyzes the reversible elimination of water²⁰⁴ probably also via a ketyl radical (Scheme 18).⁵⁴ This enzyme also occurs in *Clostridium kluyveri* during reduction of succinyl-CoA via succinic semialdehyde to butyrate.²⁰⁵ Recently, the enzyme has been detected in novel CO₂-fixation pathways occurring in Archaea, where it is involved in the conversion of succinate to two acetates.^{36,37}

4-Hydroxybutyryl-CoA dehydratase faces the same problem as 2-hydroxyacyl-CoA dehydratase because the β -hydrogen to be removed is not activated ($pK_a \approx 40$). In contrast to 2-hydroxyacyl-CoA, 4-hydroxybutyryl-CoA may be converted to the enoxy radical with an acidic β -proton ($pK_a \approx 14$) by α -deprotonation to the enolate and one-electron oxidation. Now, removal of the β -proton leads to an allylic ketyl radical that eliminates the hydroxyl group. The dienoxyl radical formed recycles the electron back to the enzyme, which protonates the dienolate to yield crotonyl-CoA.⁵⁴ This mechanism (Scheme 18) is consistent with the structure of the homotetrameric enzyme that contains in each subunit one FAD and one [4Fe–4S] cluster. As isolated, part of the FAD of the enzyme is in the semiquinone state. Full activity is obtained by brief oxidation with air, whereas longer exposure to air (5 hours at 20 °C) completely inactivates the enzyme. A controlled

Scheme 18 Proposed mechanism of the reversible dehydration of 4-hydroxybutyryl-CoA to crotonyl-CoA.

oxidation to full activity and to an EPR-silent preparation was achieved by treatment with ferricyanide [hexacyanoferrate(III)]. On addition of substrate, the EPR spectrum appeared again with the main signal of a neutral semiquinone and features attributed to partial reduction of the [4Fe–4S] cluster, but a carbon-based substrate-derived radical could not be identified.^{206,207} Chemical synthesis of stereospecifically deuterium- and tritium-labeled 4-hydroxybutyryl-CoA species revealed that the enzyme abstracts the 2*Re* and the 3*Si* hydrogen, whereas the substitution of the hydroxyl group occurs with retention of configuration.^{206,208}

The crystal structure indicated that 4-hydroxybutyryl-CoA dehydratase contains a channel between the cluster and FAD (Figure 9).²⁰⁹ The cluster is coordinated by three cysteines and a histidine. Although crystals with substrate or product could not be obtained, the fold and the position of the FAD resemble that of medium chain acyl-CoA dehydrogenase, whose structure has been solved in the presence of substrate. Therefore, 4-hydroxybutyryl-CoA was modeled into the channel, whereby similar hydrogen bonds to the thioester carbonyl could be formed as in the acyl-CoA dehydrogenase. In this orientation, the

Figure 9 Modeling of 4-hydroxybutyryl-CoA into the active site of 4-hydroxybutyryl-CoA dehydratase from *Clostridium aminobutyricum*. RCHOHCH₂ = ADP ribitol. Numbers at the amino acids denote their position in the amino acid sequence of the enzyme.

hydroxyl group replaces histidine 292 coordinated to the cluster; the 2*Re* hydrogen can be removed by this histidine and the 3*Si* hydrogen by the FAD semiquinone. The elimination of the hydroxyl group is facilitated by the cluster acting as Lewis acid. The protonated histidine probably transfers the proton to the hydroxylated cluster leading to the formation of water. Finally, the dienolate is protonated at C-4 by the conserved glutamic acid 455 to yield the methyl group (Figure 9).

Mutations of the amino acids depicted in Figure 9 yielded a completely inactive enzyme with the exception of the A460G mutant that retained 2% activity. Although the NH of a glycine residue should be a hydrogen bond donor comparable to alanine, the greater flexibility with glycine may disturb the structure of the enzyme. The other mutations strongly support the importance of His292 as a base and of the structural integrity of the [4Fe-4S] cluster. Glutamate 455 probably donates the proton for the methyl group of crotonyl-CoA and Glu257 might be involved in the proton transfer from FAD semiquinone to the solvent. The exchange of tyrosine 296 by phenylalanine reduced the activity to 1%, which might suggest participation of a tyrosyl radical in catalysis.²¹⁰

4-Hydroxybutyryl-CoA dehydratase also catalyzes the irreversible Δ -isomerization of vinylacetyl-CoA to crotonyl-CoA.²⁰⁴ This activity

is less oxygen sensitive than that of the dehydratase. Important residues are histidine 292 as proton acceptor and glutamate 455 as donor; with the mutants H292C or E455Q retaining about 1% activity. As expected, the iron sulfur cluster and FAD are not required for the isomerization. Notably, C299A and E257Q are almost fully active and are completely stable under air.²¹⁰

2.4.3 Acyl-CoA Dehydrogenases

The β -oxidation of fatty acids starts with the formation of the CoA-thioester that is dehydrogenated to the (*E*)-2-enoyl-CoA catalyzed by FAD-containing acyl-CoA dehydrogenases. The electron transferring flavoprotein (Etf) serves as an electron acceptor, which transports the electron from the dehydrogenase in the cytoplasm to the respiratory chain in the cytoplasmic membrane of bacteria and archaea or in the mitochondrial membrane of eukaryotes. There, Etf:quinone oxidoreductase catalyzes the oxidation of Etf by a quinone. Clostridia-producing short-chain fatty acids use this reaction sequence in the reverse direction, the reduction of enoyl-CoA to the saturated acyl-CoA by NADH. Recently, it has been shown that this reaction is coupled to the endergonic reduction of ferredoxin, whereby a second NADH is consumed.^{211–213} In this energetic coupling, the electrons bifurcate from NADH ($E^{\circ'} = -320$ mV) exergonically to enoyl-CoA ($E^{\circ'} = -20$ mV) and endergonically to ferredoxin ($E^{\circ'} = -420$ mV) according to following equation:

Thus, the high free energy change for enoyl-CoA reduction is conserved in the powerful reductant ferredoxin, which the cell uses either for the production of hydrogen or recycles to regenerate NADH mediated by a complex membrane protein designated as Rnf. This hetero hexameric complex, which contains riboflavin, covalently and noncovalently bound riboflavin-5'-phosphate (FMN), as well as 6–7 [4Fe-4S] clusters, acts as proton or sodium ion pump and thus contributes to the energy metabolism of the bacterial cell.^{214,215}

Scheme 19 Proposed radical mechanism for butyryl-CoA dehydrogenase after Cornforth.²¹⁶ The first proton is removed by a conserved glutamate; FAD accepts the first electron and the second proton; FADH semiquinone takes the second electron to become the hydroquinone FADH[−]. Note that the stereochemistry of the *anti*-elimination of the α - and β -protons is identical to that of 4-hydroxybutyryl-CoA dehydratase.

The generally accepted mechanism of acyl-CoA dehydrogenases starts—similar to 4-hydroxybutyryl-CoA dehydratase—with the abstraction of the α -proton, $\text{p}K_{\text{a}} = 8$, from the hydrogen bonded acyl-CoA.²¹⁷ The β -hydrogen is thought to be removed from the enolate as hydride by the flavin. Considering the mechanism of 4-hydroxybutyryl-CoA dehydratase, however, one would expect a proton-coupled one-electron transfer from the enolate to the flavin to yield the semiquinone and the product-related allylic ketyl radical followed by a second one-electron transfer to afford the flavin hydroquinone and enoyl-CoA (Scheme 19). On the basis of the observation of a putative flavin semiquinone deduced from the absorbance between 500 and 650 nm during catalysis of acyl-CoA dehydrogenases by Helmut Beinert in 1957,^{218,219} Sir John Cornforth already proposed this mechanism 50 years ago (Scheme 19).²¹⁶ Experiments with a radical trap support the idea of radical intermediates,²²⁰ but EPR spectroscopy detected no signal.²¹⁹ Furthermore, the putative semiquinone turned out to represent a tight charge-transfer complex between FADH[−] and the product enoyl-CoA.²¹⁷

2.4.4 Etf and Electron Bifurcation

The redox potentials of flavins are extremely dependent on their surroundings. While free flavin exhibits $E^{\circ'} = -230$ mV (semiquinone/hydroquinone) and $E^{\circ'} = -170$ mV (quinone/semiquinone),²²¹ the values for flavodoxin from *A. fermentans* are $E^{\circ'} = -430$ and -60 mV, respectively.¹⁸⁹ Cell extracts from *A. fermentans*¹⁸⁹ and *Fusobacterium nucleatum* (D. Brügel and W. Buckel, unpublished data) prepared

under anaerobic conditions contain flavodoxin as a stable blue semiquinone radical. FAD within an acyl-CoA dehydrogenase shows a typical $E^{\circ'} = -145$ mV (quinone/hydroquinone), which on substrate addition increases to -26 mV.²²² These considerations allow the proposal of a mechanism for electron bifurcation catalyzed by the clostridial complex of Etf and butyryl-CoA dehydrogenase (Scheme 20). The heterodimeric Etf, which probably resembles that of *Megasphaera elsdenii*,²²³ contains two FAD molecules in different surroundings, say β -FAD in the β -subunit and γ -FAD in the γ -subunit. β -FAD should have a negative redox potential (quinone/hydroquinone; $E^{\circ'} = -500$ mV). Thus, it cannot be reduced by NADH ($E^{\circ'} = -320$ mV) to β -FADH[−] unless γ -FAD accepts one electron, whereas the remaining electron reduces ferredoxin ($E^{\circ'} = -420$ mV). γ -FAD ($E^{\circ'} = -60$ mV) takes up only one electron, because its semiquinone/hydroquinone transition for a second electron is much too negative ($E^{\circ'} < -500$ mV). The electron is further delivered to the FAD of acyl-CoA dehydrogenase. This process is repeated to obtain the FADH[−] (hydroquinone) state in the dehydrogenase and a second molecule of reduced ferredoxin.

2.4.5 DNA Photolyase

In contrast to dry DNA in bacterial spores (see SAM radical enzymes), irradiation of DNA in the cytoplasm of a cell with UV-B light (290–320 nm) causes two adjacent thymidine residues to form a cyclobutane–pyrimidine dimer (CPD) by [2+2] cyclophotoaddition. DNA photolyase repairs this lesion in a radical reaction driven by blue light (350–450 nm). The enzyme from *E. coli* contains

Scheme 20 Proposed mechanism of electron bifurcation. Green: proteins; blue: oxidized forms; magenta: reduced by one electron; orange: reduced by two electrons.

methylenetetrahydrofolate ($CH_2=FH_4$) and FAD as prosthetic groups. For catalysis, FAD needs to be in the reduced anionic state ($FADH^-$), which absorbs almost no blue light. The $CH_2=FH_4$ group ($\lambda_{\max} = 380\text{ nm}$) acts as light antenna and transfers the energy to $FADH^-$ to yield the excited state $FADH^{-*}$.²²⁴ Binding of the lyase to the DNA lesion results in flipping of CPD into the active site of the enzyme.²²⁵ Then, $FADH^{-*}$ transfers a high-energy electron to CPD to form a ketyl radical at C-4, adjacent to the cyclobutane ring. Similar to 2-hydroxyacyl-CoA dehydratases, the ketyl radical may act as a nucleophile that cleaves the 5–5' and 6'–6 bonds of the cyclobutane ring to give a resonance-stabilized ketyl radical and one restored thymidine residue. Finally, the electron recycles back to the transiently formed $FADH$ semiquinone to yield the second restored thymidine and regenerated $FADH^-$. Thus, the next photon can drive another turnover (Scheme 21).

A similar mechanism cleaves the (6–4) lesion in DNA (Scheme 22). Again, one high-energy electron from $FADH^{-*}$ repairs the lesion in two-electron steps.²²⁶ The lesion derives from [2+2] cyclopho-toaddition of the 5'=6' double bond of one thymidine residue at the C-4 carbonyl group of the other thymidine residue, probably with a four-membered oxetane ring as an intermediate. Thereby, the oxygen is transferred without solvent exchange. Hence, the mechanisms of the photolyases and 2-hydroxyacyl-CoA dehydratases are similar. A high-energy electron forms a substrate-derived ketyl

radical, and the most likely concerted reaction proceeds to a product-related ketyl radical that recycles the electron back for the next turnover. Only in one aspect do the mechanisms differ: While the photolyases require light energy for every turnover, the 2-hydroxyacyl-CoA dehydratases are able to recycle the electron 10^4 times without external energy input. With photolyase, the energy difference between the two radicals is probably too high to allow recycling in the dark as in the dehydratase. In addition, the lifetime of $FADH^{-*}$ might not be long enough for the enzyme to find another lesion.

Homologues of the DNA photolyase that repairs the CPD lesion are cryptochromes, the blue light receptors of many organisms.²²⁷ The N-terminal part contains the domains that bind methylenetetrahydrofolate and FAD, whereas the C-terminal part conveys the specific function of the receptor to other proteins and, in case of animals, finally to the nervous system. Experiments with migrating birds suggest the involvement of cryptochromes in magnetoreception, a compass by which these animals achieve remarkable intercontinental travel.²²⁸ The receptor is a radical pair that can exist in the triplet and singlet states, whose interconversion and life times are influenced by the magnetic field.²²⁹ Irradiation of the oxidized FAD with blue light forms the radical pair. Thereby, FAD is reduced to the anionic flavin semiquinone by an electron from one of three conserved tryptophans of the protein that is oxidized to a cation radical. Hence, radical pair formation is involved in the reduction of FAD to

Scheme 21 Formation of thymidine dimers in DNA by irradiation with UV-B and repair by catalysis with DNA photolyase, energized by UV-A.¹⁸¹

Scheme 22 Formation and enzymatic cleavage of the DNA (4-6)-photoproduct.¹⁸¹

the semiquinone, whereas the photolyase uses the excited state of the fully reduced $\text{FADH}^{\bullet-}$.

2.4.6 Chorismate Synthase and 2-Haloacrylate Hydratase

The amino acids phenylalanine, tyrosine, and tryptophan are synthesized by the so-called shikimate pathway. At the intermediate chorismate, as indicated by its Greek name, the path diverts either to prephenate, the precursor of phenylalanine and tyrosine, or to tryptophan via anthralinate. The synthesis of chorismate from 5-enolpyruvoylshikimate-5-phosphate by *anti*-1,4-elimination of phosphate is catalyzed by a reduced riboflavin-5'-phosphate (FMNH^-)-containing enzyme (Scheme 23). The reaction attracted much interest, because

it was expected that the apparently simple 1,4-elimination of phosphate should occur with *syn*-geometry.^{230,231} This was deduced from the observed *anti*-1,2-elimination of water from many hydroxy acids (not hydroxyacyl-CoA!). However, in contrast to elimination of water from 3-hydroxy acids, the hydrogen to be removed as proton is not acidic. Therefore, it appears most likely that the enzyme proceeds via a radical mechanism, analogous to that of 2-hydroxyacyl-CoA dehydratases. A one-electron transfer from FMNH^- to the double bond of the substrate 3-enolpyruvylshikimate-5-phosphate would yield the flavin semiquinone and a radical anion that readily eliminates the phosphate. The resulting allyl radical is deprotonated to an allylic radical anion that is finally oxidized to the product.^{4,232}

A similar mechanism most likely operates with the FADH^- -dependent 2-haloacrylate hydratase that

Scheme 23 Reaction catalyzed by chorismate synthase.

Scheme 24 Proposed mechanism for the hydration of 2-chloroacrylate to pyruvate and HCl.

catalyzes the hydration of 2-chloroacrylate to pyruvate and chloride. A simple hydration of chloroacrylate would lead to 2-chloro-3-hydroxypropionate, which is not observed.²³³ Addition of one electron from FADH^- to 2-chloroacrylate would cause an “Umpolung” and directs the proton to the methylene group. The resulting 2-chloropropionate radical returns the electron back to the flavin semiquinone to yield a carbocation that reacts with water to 2-chloro-2-hydroxypropionate. α -Elimination of HCl affords the final product pyruvate (Scheme 24).

2.5 Reduction of Aromatic Compounds

Although many useful natural products are aromatic compounds, the formation of benzene and polycyclic aromatic compounds in combustion processes is responsible for environmental contamination with substances that are potentially damaging to all forms of life. Fortunately, mechanisms exist

for the destruction of these pollutants. In the aerobic metabolism of aromatic compounds, degradation is initiated by addition of an oxygen atom, mediated by cytochrome *P*450 mono-oxygenases,²³⁴ or dioxygen catalyzed by dioxygenases, to the ring π -system. In contrast, anaerobic bacteria abolish aromaticity *without* the aid of (di)oxygen and do so by reductive reactions. For benzoic acid, there are two classes of enzymes that are key to the reduction of its CoA ester.²³⁵ In the best studied example from *Thauera aromatica*, de-aromatization of benzoyl-CoA is effected by a class I BCR.²³⁶ This type of BCR contains four subunits ($\alpha\beta\gamma\delta$) and three [4Fe–4S] clusters and is extremely oxygen sensitive. The α - and δ -subunits each bind a molecule of ATP and effect electron transfer to benzoyl-CoA at the active site, which is housed within the $\beta\gamma$ -subunits. The functions of the four subunits were deduced from their sequence similarity with the 2-hydroxyacyl-CoA-dehydratases.²³⁷ The α - and δ -subunits are related to the activator and most likely coordinate one of the three [4Fe–4S] clusters in between. The β - and γ -subunits that are related to the actual dehydratase contain the conserved cysteines of the α - and β -clusters of the dehydratase.¹⁹⁸

The two-electron reduction of benzoyl-CoA utilizes reduced ferredoxin, hydrolyzes the two molecules of ATP and affords cyclohexa-1,5-diene-1-carboxyl-CoA via a stereoselective *trans*-dihydro addition (Scheme 25a).²³⁸ This reaction is astonishing because its chemical analogy, the “Birch reduction” of benzenoid compounds employing sodium in liquid ammonia, has a redox potential of circa -3 V .²³⁵ The class I BCR is quite “catholic” in that it reduces a range of substrate analogs (i.e., benzoyl-CoA substituted with F, Cl, CH_3 , OH, and NH_2), and the benzene ring can be replaced by a pyridine.²³⁶

Scheme 25 Reaction catalyzed by class I BCR (a, Fd = ferredoxin; the stereochemistry of addition is shown by the red color) and class II BCR (b, A_{red} and A_{ox} = electron donor/acceptor).

The same overall reaction but with different cofactors (Scheme 25b) is accomplished by the class II BCR from, for example, *Geobacter metallireducens*, which is an ATP-independent enzyme containing tungstopterin [W^V], one [3Fe-4S] cluster, three [4Fe-4S] clusters, and selenocysteine.^{235,239} While class I BCRs are irreversible, the class II version is fully reversible. With $E^{\circ'} = -622$ mV, this BCR exhibits a midpoint redox potential significantly lower than that of other redox enzymes.²³⁵ While in class I BCR, this low redox potential is achieved by coupling to the hydrolysis of two ATP, how this is accomplished in class II BCR remains an enigma. It has been speculated that the ATP-independent electron transfer to the aromatic ring is driven either by an electrochemical membrane potential or by electron bifurcation (see Section 2.4.4) from ferredoxin ($E' = -500$ mV) to NAD⁺ ($E' = -270$ mV).^{235,239}

A mechanism for reduction of benzoyl-CoA by BCR has been proposed that is analogous to the one well established for the Birch reduction (Scheme 26).²³⁶ The first step is electron addition to give a radical anion analogous to the ketyl radicals discussed in Section 2.4. This is the most difficult step and is presumably achieved by a sufficiently low redox potential (see above) applied to a sufficiently electron-deficient substrate. The intermediate radical anion is intrinsically stable as a highly delocalized ketyl species and could be further stabilized by interactions with active site residues, for example, hydrogen bonding to the carbonyl oxygen.⁵⁴ Protonation of this intermediate, a further electron addition, and another protonation affords cyclohexa-1,5-diene-1-carboxyl-CoA. Presumably, the observed regio- and stereochemistry is controlled by appropriately positioned groups at the BCR active site. Notably, the proposed mechanism

Scheme 26 Mechanism for BCR reduction of benzoyl-CoA.

of the phylogenetically related 2-hydroxyacyl-CoA dehydratases also starts with a ketyl radical (Schemes 16 and 17).^{82,193} Benzoyl-CoA can be regarded as a central intermediate in the anaerobic catabolism of many benzenoid compounds. For example, phenol is converted to benzoyl-CoA by a sequence of phosphorylation, carboxylation coupled to phosphate hydrolysis, and deoxygenation of 4-hydroxybenzoyl-CoA.^{240–242} 4-Hydroxybenzoyl-CoA reductase, which catalyzes this deoxygenation to benzoyl-CoA, contains molybdopterin, FAD, and a [4Fe-4S] cluster with ferredoxin as reductant. The reduction probably involves a ketyl radical⁸² and Mo^V.²⁴² The degradation of naphthalene proceeds via 2-naphthoyl-CoA, which is a substrate for naphthoyl-CoA reductase (NCR) and yields tetrahydronaphthoyl-CoA.²⁴³ The mechanism of NCR is expected to be similar to that of BCR, that is, electron transfers and protonations, with an intermediate ketyl radical.

Similar to BCRs, the reduction of the C₁₇=C₁₈ double bond of the D-ring of the aromatic 22- π system of protochlorophyllide by NADPH requires

Scheme 27 Two types of protochlorophyllide reductases. Angiosperm plants use NADPH and light; all other organisms take reduced ferredoxin (Fd^-) and ATP.

energy either from light or ATP (Scheme 27). While angiosperm plants use light, all other chlorophyll and bacteriochlorophyll-containing organisms reduce protochlorophyllide in the dark with ferredoxin but need ATP for this process. The enzyme is not only functionally but also phylogenetically related to nitrogenase (NifDK)₂ and its Fe protein (NifH)₂.²⁴⁴ It consists of a homodimeric Fe protein (BchL)₂ with one [4Fe–4S] cluster between the subunits and a heterotetrameric actual reductase (BchBN)₂, which contains 2×1 [4Fe–4S] cluster between the BchB and BchN subunits but lacks the P cluster and the MoFe cofactor.^{245–247} Therefore, the reductase is more closely related to the scaffold protein of nitrogenase (NifEN)₂, on which the MoFe cofactor is assembled before it is transferred to the nitrogenase MoFe protein (NifDK)₂.²⁴⁸ A similar enzyme system, chlorophyllide reductase composed of (BchX)₂ + (BchYZ)₂, catalyzes, in addition, the reduction of the opposite double bond in ring B of chlorophyllide to yield bacteriochlorin, the precursor of bacteriochlorophylls. Although EPR spectroscopy could not detect radical intermediates in the ATP-dependent reductases, there is evidence that the two electrons required for reduction are transferred one by one, in the same way as to nitrogenase.²⁴⁴

2.6 Isoprenoid Biosynthesis

The biosynthesis of isoprenoids from deoxyxylulose-5-phosphate in green algae, plant chloroplasts, pathogenic bacteria, and in

the malaria parasite *Plasmodium falciparum* but not in animals and fungi, occurs via the methyl-D-erythritol-2,4-cyclodiphosphate (MEP) pathway, rather than by the well-known mevalonate pathway.²⁴⁹ Like the mevalonate pathway, the MEP pathway produces isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAPP).²⁵⁰ The putative radical enzymes (*E*)-4-hydroxy-3-methylbut-2-enyl diphosphate synthase (abbreviated as GcpE or IspG) and (*E*)-4-hydroxy-3-methylbut-2-enyl diphosphate reductase (LytB or IspH) catalyze steps in the MEP pathway. They have been isolated from *E. coli* and other organisms, and both contain an oxygen-sensitive [4Fe–4S] cluster.^{251,252}

GcpE/IspG catalyzes the conversion of methylerythritol-2,4-cyclodiphosphate (MECycloPP) to (*E*)-4-hydroxy-3-methylbut-2-enyl diphosphate (HMBPP), while LytB/IspH converts the latter to a mixture of IPP and DMAPP. GcpE/IspG and LytB/IspH are coupled with a system that reduces the oxidized [4Fe–4S]²⁺. In *E. coli*, flavodoxin/ferredoxin reductase and NADPH fulfill this function. The reduced [4Fe–4S] cluster in GcpE/IspG was suggested to effect two one-electron transfers generating intermediate radicals (Scheme 28). Cleavage of the cyclodiphosphate ring to a tertiary carbocation is followed by one-electron reduction to give a β -hydroxyalkyl radical that eliminates the C-3 hydroxyl group in the manner of RNR or diol dehydratase (see above). The resulting alkene radical cation is reduced to an alkene by a further one-electron transfer from the cluster. Studies of GcpE/IspG by EPR and

Scheme 28 Hypothetical biogenetic pathway for the reactions catalyzed by GcpE and LytB ("E" represents an electrophilic entity that might be a Fe of the [4Fe-4S] cluster).

ENDOR detected several paramagnetic species on the reaction pathway and they all interacted with the Fe-S cluster.²⁵³ The data were interpreted as evidence for substrate binding to the cluster and its involvement in the elimination of substrate hydroxyl. A quite different thesis was put forward from the results of a similar spectroscopic study aided by isotopic labeling of MEP with ²H, ¹³C, and ¹⁷O.²⁵⁴ In this case, a series of intermediate metalocycles were proposed and the pathway was claimed to be supported by the finding that propargyl diphosphate is a potent inhibitor of GcpE/IspG (*K_i* ~ 300 nM), possibly by formation of a ferracyclopropene.

(*E*)-4-Hydroxy-3-methylbut-2-enyl diphosphate reductase (LytB/IspH) reduces HMBPP to a mixture of IPP and DMAPP via two successive one-electron transfers from the reduced [4Fe-4S] cluster. This yields, probably via radicals, an intermediate allylic anion, which is protonated either at C-2 affording IPP or at C-4 giving DMAPP (Scheme 28). The removal of the hydroxyl group from HMBPP might be assisted by an interaction with the Fe-S cluster (cf. 4-hydroxybutyryl-CoA above). Mössbauer studies of LytB/IspH revealed that a [4Fe-4S]²⁺ cluster is bound to the protein by three sulfur atoms from cysteines and by additional nitrogen and/or oxygen ligands surrounding a hexacoordinate iron centre.²⁵² Five crystal structures were obtained for LytB/IspH bound to substrate, products, or diphosphate and were interpreted as supporting the

mechanism outlined and shown in Scheme 28.²⁵⁵ Activation of substrate hydroxyl by coordination to an iron centre was compared with the similar mode of action of aconitase. For LytB/IspH, expulsion of the hydroxyl group is assisted by a proton-coupled electron transfer to the substrate double bond. Again, an opposing proposition suggested a role for organometallic species in the mechanism of LytB/IspH.²⁵⁶ Arising from this study were the "first potent IspH inhibitors," for example, an alkynyl diphosphate with IC₅₀ = 0.45 μM.

Inhibitors of the MEP pathway are potential selective drugs against pathogenic bacteria and certain parasites. In attempt to target the pathway at an earlier point, a high-throughput screen of a large library of compounds identified thiazolopyrimidines as modest inhibitors (IC₅₀ = low micromolar) of methyl-D-erythritol-2,4-cyclophosphate synthase (IpsF) from *Arabidopsis thaliana*.²⁵⁷

2.7 Pseudo Radical Enzymes

The so-called pseudo radical enzymes mediate the main reaction on the catalytic pathway in two-electron steps, whereas the subsequent recycling of the cofactors occurs by two one-electron transfers. This section deals with two examples of this group, the degradation and formation

of 2-oxoacids and the reversible reduction of methyl-coenzyme M (methyl-CoM) to methane.

2.7.1 2-Oxoacid Dehydrogenases/Oxidases

2-Oxoacids are important intermediates in catabolism and anabolism of sugars and amino acids. In chemotrophic organisms, 2-oxoacids are usually degraded to acyl-CoA and a C₁ compound, either CO₂ or formate. In anaerobic autotrophic organisms, 2-oxoacids are synthesized by reductive carboxylation of acyl-CoA. The enzymes involved are pyruvate formate lyase, a glycyl-radical enzyme, which has been discussed in a previous section, 2-oxoglutarate and pyruvate dehydrogenases, pyruvate oxidase, as well as 2-oxoglutarate and pyruvate:ferredoxin oxidoreductases (2-oxoglutarate and pyruvate synthases). With the exception of pyruvate formate lyase, these enzymes require ThDP as cofactor, which forms an adduct with the 2-oxoacid. With pyruvate as substrate, the 2-lactyl-ThDP formed resembles an imine of a 3-oxoacid, which readily decarboxylates to α -hydroxyethyl-ThDP.²⁵⁸ While these two-electron steps occur with all ThDP-dependent enzymes, the subsequent oxidation to acyl-CoA is different. In the reversible pyruvate ferredoxin oxidoreductase, the first electron transfer to a [4Fe-4S] cluster and then to ferredoxin generates a relatively stable thiamin-based radical, which was one of the first radicals observed in enzymatic catalysis.²⁵⁹ This exciting result was probably due to the fact that the enzyme from the facultative anaerobe *Halobacterium salinarum* is much more tolerant to dioxygen than those from strict anaerobes. Later the same radical could be observed and structurally characterized in crystals of the pyruvate:ferredoxin oxidoreductase from the sulfate reducer *Desulfovibrio africanus*.²⁶⁰ The second electron is only transferred in the presence of CoA leading to acetyl-CoA. Model studies have shown that acetyl-ThDP is a poor electrophile, unable to acetylate CoASH at a reasonable rate. Therefore, the second electron derives from CoASH that is converted to a thiyl radical, which recombines with the thiamin-based radical to yield acetyl-CoA and regenerate the cofactor.

The FAD and ThDP containing pyruvate oxidase catalyzes the irreversible dioxygen- and inorganic

phosphate-dependent conversion of pyruvate to H₂O₂ and acetyl-phosphate. Again, in the absence of phosphate, the stable thiamin-based radical was obtained.²⁵⁸ The most elaborate enzyme of this group is the huge enzyme complex pyruvate dehydrogenase, composed of a decarboxylase with ThDP, a lipoamide-containing transacetylase with covalently bound lipoamide, and an NAD⁺-dependent and FAD-containing dehydrogenase. The initially formed hydroxyethyl-ThDP donates both electrons, apparently in one-electron steps, to the protein-bound lipoamide (see Section 2.3.2.3 for lipoamide biosynthesis via a SAM radical enzyme). Chemical considerations indicate that the strained five-membered dithiolane ring of lipoamide is not amenable to a two-electron reduction (Perry A. Frey, personal communication). Furthermore, the thiamin-based radical has been observed by EPR spectroscopy during catalysis of the *E. coli* enzyme (Kai Tittmann, Antonio J. Pierik, and Wolfgang Buckel, unpublished data). Concomitant with the second electron transfer, the acetyl moiety and the proton are combined to yield S⁶-acetyl-dihydrolipoamide. In the second step, the acetyl group is transferred to CoASH, yielding acetyl-CoA. The final re-oxidation of dihydrolipoamide is catalyzed by the FAD-containing lipoamide dehydrogenase using NAD⁺ as electron acceptor, certainly via FAD semiquinone as intermediate.

2.7.2 Methyl-Coenzyme M Reductase

Methyl-CoM reductase from methanogenic Archaea mediates the formation of methane from methyl-S-CoM (CH₃-S-CoM) and coenzyme B (CoB-SH). The enzyme contains nickel bound within factor 430 (F₄₃₀), a yellow Ni-porphyrinoid with λ_{max} 430 nm.²⁶¹ Methane could arise by homolysis of a labile methyl-Ni σ -bond, although a methyl radical has not been detected. Most experimental data collected with the reductase fit a mechanism that starts with nucleophilic attack of Ni(I) at the methyl group of methyl-CoM. Protonation of the resulting methyl-Ni^{III}-F₄₃₀ releases methane, and Ni(I) is regenerated by two one-electron reductions from CoB-SH to form CoB-S-S-CoM via thiyl and sulfuranyl radicals.²⁶² Recently, evidence has been obtained

that methyl-CoM reductase is also able to catalyze the oxidation of methane, just the reverse of its formation. This is the first example of the cleavage of the strongest known C–H bond without oxygen. Compared to a methyl group in a saturated hydrocarbon, the C–H bond of methane is 18 kJ mol^{−1} stronger.²⁶³

Recently, another problem of methanogenesis has been solved, the source of the reduced ferredoxin ($E' = -500$ mV) to drive the first step, the reduction of CO₂ to formyl-methanofuran. While in cytochrome-containing methanogens, for example, *Methanosarcina barkeri*, this is achieved via an electrochemical H⁺ gradient (proton motive force), in cytochrome-less methanogens, for example, *Methanothermobacter marburgensis*, the energy-conserving heterodisulfide reductase is a soluble enzyme that cannot form such a gradient. Experiments with the isolated hydrogenase/heterodisulfide complex from *M. marburgensis* revealed that even low hydrogen concentrations (10 Pa; $E' = -300$ mV) are able to reduce ferredoxin if coupled with the reduction of the heterodisulfide ($E^{\circ'} = -140$ mV).^{264,265} Interestingly, the core of the FAD- and [4Fe–4S] cluster-containing heterodisulfide complex resembles that of the core of class II BCR complex. This similarity led to the speculation that the low redox potential required for the reduction benzoyl-CoA is also achieved by electron bifurcation (see Section 2.4.4).

2.8 Radical Reactions Initiated by Oxygen

This review has mainly focused on enzymes that generate radicals without using the diradical oxygen. The only exception reported so far is class I RNR, which employs oxygen for generation of a tyrosyl radical that is propagated over a distance of 35 Å to the active site cysteine to form a thiyl radical.²⁶⁶ Although this tyrosyl radical is exceedingly stable and was the first radical to be discovered in an enzymatic reaction, in most oxygen-dependent reactions, radicals were only detected by indirect methods due to their short lifetimes. An example is isopenicillin synthase that contains a nonheme Fe(II) species at the active site. The enzyme catalyzes the formation of the penicillin core of isopenicillin N from the tripeptide δ -(L- α -aminoadipoyl)-L-cysteinyl-D-valine. This is

a four-electron oxidative bicyclization, resulting in formation of both the β -lactam and thiazolidine rings of the isopenicillin N product. The complete reduction of dioxygen to water via a Fe peroxide and a Fe(IV) oxo species drives formation of the strained bicyclic ring system.²⁶⁷ Each species is thought to abstract a hydrogen atom necessary for each ring closure.

In many oxidases, oxygenases, and hydroxylases, flavin cofactors are involved which are transiently reduced to the semiquinone radical. The oxidation of primary amines to aldehydes and ammonia catalyzed by amine oxidase is proposed to proceed via one-electron transfer from the amine to FAD, yielding the amine radical cation and the semiquinone, which equilibrates with an adjacent tyrosine residue. The second electron transfer affords the imine that hydrolyzes to the aldehyde and ammonia. Finally, oxygen reacts with resulting flavin hydroquinone (FADH₂) to recycle the initial quinone state of FAD, whereby hydrogen peroxide is produced. The detection of a tyrosyl radical during catalysis is of interest because the redox potentials of FAD and tyrosine differ by about 1.0 V. Presumably, tunneling effects are responsible for this surprising result.²⁶⁸

2.9 Biotechnological Applications

There is only one radical enzyme that is currently applied in biotechnology, the coenzyme B₁₂-dependent glycerol dehydratase.²⁶⁹ The enzyme catalyzes the dehydration of glycerol to 3-hydroxypropanal that is reduced by a subsequent enzyme to 1,3-propanediol, a valuable monomer for polyesters, from which fabrics are made. The company Dupont advertises the fabrics as “Cloths from Corn.” The coenzyme B₁₂-dependent enzyme has the disadvantage of rapid inactivation during catalysis, which has to be overcome by adding expensive vitamin B₁₂ to the growth medium. The more recently discovered glycy radical enzyme glycerol dehydratase may solve this problem.²⁷⁰ The process, however, has to be performed under strict anaerobic conditions, whereas the B₁₂-dependent enzyme tolerates some oxygen.

An old dream in biotechnology is the production of acrylate via lactate from sugars. Although the radical enzyme lactyl-CoA dehydratase has been available for some time,¹⁸⁵ its extreme oxygen sensitivity and the unfavorable equilibrium

($K' = [\text{acrylyl-CoA}]/[(R)\text{-lactyl-CoA}] = 0.02$)¹⁸⁷ prevented its application. The thermodynamic problem appeared to be tractable by converting acrylyl-CoA to 3-hydroxypropionyl-CoA catalyzed by crotonase. More than 10 years ago, the food company Cargill, Minneapolis, USA, started a program to produce 3-hydroxypropionate (3-HP) in *E. coli*. 3-HP is easily dehydrated to acrylate by heating in acid. Because lactate could not be completely converted to 3-HP, probably again because of thermodynamic reasons, the company abandoned this project and started to convert the SAM-dependent radical enzyme lysine-2,3-aminomutase into alanine-2,3-aminomutase by specific and random mutagenesis, which has been achieved. The new pathway starts from glucose to pyruvate, which is transaminated to α -alanine. The resulting β -alanine readily affords 3-HP via malonic semialdehyde. An alternative nonradical pathway to 3-HP could proceed via pyruvate, oxaloacetate, and aspartate, which can be α -decarboxylated to β -alanine. The authors of this review are not aware which routes are currently pursued by the biotechnological industry.

The genes coding for (*R*)-2-hydroxyglutarate dehydrogenase, glutaconate-CoA transferase, and the radical enzyme (*R*)-2-hydroxyglutaryl-CoA dehydratase with its activator or “archerases” from *A. fermentans* and *C. symbiosum* were expressed in *E. coli* and led to the production of (*E*)-glutaconate from glucose, though at the low level of 3 mM.²⁷¹ Currently, attempts are made to reduce the intermediate glutaconyl-CoA to glutaryl-CoA, which would yield glutarate, a dicarboxylic acid for the production of polyesters. Experiments on the substrate specificity of the transferase and dehydratase indicated that these enzymes could also be used to synthesize adipic acid, a constituent of nylon-6,6, if *E. coli* can be engineered to provide the necessary (*R*)-2-hydroxyadipic acid.²⁷²

Many bacteria store surplus carbon as poly-3-hydroxybutyrate (PHB), which is a useful biodegradable polymer for making disposable bottles, cups, and so on. Copolymerization of 3-hydroxybutyryl-CoA with its 4-hydroxy isomer changes the physical properties of the polymer and makes it more suitable for specific applications. This has been achieved by adding 4-hydroxybutyrate to the growth medium of the PHB-producing bacterium. A more elegant method would be via expression of the gene coding for the radical enzyme

4-hydroxybutyryl-CoA dehydratase.²¹⁰ The enzyme may take crotonyl-CoA from the central metabolism and hydrate it to 4-hydroxybutyryl-CoA, ready for polymerization. An alternative nonradical pathway from succinyl-CoA of the Krebs cycle to 4-hydroxybutyryl-CoA uses three enzymes from *C. kluyveri*.²⁷³

3 EVOLUTIONARY ASPECTS

One theory of the origin of biochemical pathways proposed an iron–sulfur world, dominated by one-electron transfers mediated by iron–sulfur clusters.²⁷⁴ Thus, radical reactions may have been widespread in the primeval world, and some have survived in extant anaerobic organisms and to a lesser degree in aerobes. Radical enzymes that only contain iron–sulfur clusters are GcpE and LytB of the nonmevalonate isoprenoid biosynthesis pathway, as well as the “archerases” of 2-hydroxyacyl-CoA dehydratases and class I BCRs on the one hand and the light-independent protochlorophyllide and chlorophyllide reductases related to nitrogenase on the other hand. In the primeval world, the precursors of these enzymes might have used different substrates and even have catalyzed other reactions, cf. dehydratases versus reductases. Nevertheless, they give an idea about the broad spectrum of “iron-only” radical enzymes devoid of any other cofactor. The “archerases” are homodimeric proteins that contain a $[4\text{Fe}-4\text{S}]^{1+}$ cluster between the subunits and bind ATP. The electron is injected into the target enzyme at the expense of ATP, like an archer shooting arrows (see Section 2.4). This system, by which the electron gains a very negative redox potential, has two different origins, which during evolution converged to similar functions. The “archerases” of 2-hydroxyacyl-CoA dehydratases and class I BCRs originated from the ATP kinase/actin family,²⁰⁰ whereas those of nitrogenase, as well as the light-independent protochlorophyllide and chlorophyllide reductases, are related to the Walker motif containing ATP-dependent enzymes.²⁷⁵

The cofactor-requiring radical enzymes probably appeared later in evolution than the “iron-only” radical enzymes. The biosynthesis of the radical generator coenzyme B₁₂ involves six SAM-dependent methylations.²⁷⁶ Therefore, it can be concluded

that SAM radical enzymes could have preceded those which depend on adenosylcobalamin. Note that the biosynthesis of SAM not necessarily requires cobalamin, because there is an alternative but less efficient Zn-containing methyl transferase, that is, a methionine synthase.²⁷⁷ Despite its exceedingly complex biosynthesis, the advantage of coenzyme B₁₂ over SAM is its oxygen tolerance, especially in reversible radical recycling reactions, and its possible involvement as conductor rather than spectator in the mutase reactions.³² There is structural evidence, however, that SAM and coenzyme B₁₂ radical enzymes are related. Evolution conserves structural elements much longer than amino acid sequences. As mentioned above, the overall folds of the SAM radical enzyme ThiC, involved in thiamin biosynthesis, and the adenosylcobalamin-dependent glutamate mutase are very similar. Just the radical-generating subdomains/subunits have been exchanged during evolution. Most likely the coenzyme B₁₂-binding subunit replaced the SAM domain.¹⁵³

Riboflavin, present in FMN and FAD, is certainly an early cofactor, which is necessary for hundreds of different enzymes. In this review, only a few of those have been mentioned, in which radicals have been detected or are most likely involved. Probably in most, if not all flavin enzymes, a semiquinone radical intermediate is involved, which in most cases escapes detection due to its short lifetime.

Many cofactors and active sites of enzymes are synthesized by SAM radical enzymes, which supports the idea of an early appearance of this type of radical generation, as for biotin, lipoamide, thiamin, molybdopterin, heme, and chlorophyll, as well as [FeFe]hydrogenase, [Fe]hydrogenase, PQQ enzymes, sulfatases, and glycyl-radical enzymes. The anaerobic pathway of chlorophyll biosynthesis needs coenzyme B₁₂ in addition to SAM. Among the most intriguing radical reactions are those that lead to thiamin,^{148,151} a cofactor of pyruvate synthesis and catabolism that is of central importance to metabolism. It has been proposed that pyruvate synthesis from an acetyl-thioester and CO₂ is one of the key reactions involved in the autotrophic origin of life.²⁷⁴ Probably in the primeval world, cyanide or similar compounds were used instead of thiamin. Addition of cyanide to carbonyl group causes the same “Umpolung” as thiamin, exemplified by the benzoin condensation. Thiamin has the advantage that the $pK_a = 18$ of the proton at C-2

of the thiazole ring is much higher than that of HCN ($pK_a = 9$). When bound to the protein, however, the proton at C-2 of ThDP can be removed, because the pyrimidine amino group is oriented into a position where it acts as a base.²⁷⁸ Thus, the metabolism of 2-oxoacids and ketosugars can be controlled by regulation of the activities of the corresponding enzymes.

4 CONCLUDING COMMENTS

After the publications^{40,102,216,259,279,280} of the pioneers of radical enzymes, the field developed slowly at first, but then markedly accelerated in the past two decades.¹⁸¹ Not even mature, the field has now sired some of the most mesmerizing reactions in biochemistry. The evolution of life quite possibly depended on radical reactions and its continuation most certainly requires them. The discovery of new radical enzymes, exhibiting extraordinary “molecular acrobatics” that are guaranteed to satiate our scientific curiosity, seems assured. And the translation of some of the pathways into laboratory and industrial synthetic processes will benefit mankind.

ACKNOWLEDGMENTS

Dedicated to Professor Albert Eschenmoser on the occasion of his 85th birthday.

The priority program 1319 “Biological transformations of hydrocarbons without oxygen: from the molecular to the global scale” of the Deutsche Forschungsgemeinschaft and the Max-Planck-Society have funded this work.

1 INTRODUCTION

In recent years, theoretical calculations have become an important part of mechanistic chemistry. Whether serving for the validation or modification of existing mechanistic proposals, or for the predictive development of new mechanisms, it is clear that the theoretical approach has much to offer.¹ This is particularly true in the case of highly reactive short-lived intermediates such as radicals, for which it is often difficult to obtain detailed information through experiment alone. As will be evident throughout this article, the study of radicals is a challenging field. Thus, the ability to achieve molecular-level insight via computational modeling of complex biological processes is truly invaluable. Theoretical modeling allows the calculation of structures, reaction energies, barriers, rates, reduction potentials, spectroscopic parameters, and many other molecular properties (see **Radical Stability—Thermochemical Aspects**). In the modeling process, however, it is necessary to construct a model system that is sufficiently small to allow accurate calculations but sufficiently large to include the catalytically essential portions of the enzyme, which may not always be a trivial task. Because the computational costs rise rapidly with the size of the system being investigated, finding the appropriate balance between size and accuracy is of utmost importance.

The chemical models that are constructed to describe biophysical phenomena vary greatly. For instance, one may examine isolated gas-phase substrates and reaction intermediates (i.e., in the absence of bulk enzyme), with an aim of capturing the intrinsic reactivity.^{2,3} Such an approach enables one to quantify with high precision the extent to which it is necessary for the enzyme to activate its substrate and transform intermediates. In an approach of this kind, it may also be desirable to include in the model additional species that mimic active-site amino acids so as to gain insight into their possible function. These so-called small models are particularly useful because specific interactions that may be responsible for facilitating the reactions can be turned “on” or “off” straightforwardly.

It is sometimes desirable to move beyond a small-model approach to capture longer range effects. The development of hybrid quantum mechanics/molecular mechanics (QM/MM) procedures is therefore another popular means of gaining insight into complex biophysical phenomena.^{4,5} The basic premise of the QM/MM scheme is to combine the accuracy of QM methods with the speed of MM methods in an effort to increase the efficiency of a theoretical investigation for larger systems. QM/MM schemes separate the overall system into distinct QM and MM regions such that

the chemically active part, which requires a sophisticated electronic structure treatment (for bond breaking, bond forming, charge transfer, and/or electronic excitation processes), is described in the QM region, while the MM region encompasses the remainder (e.g., protein plus solvent). The MM region is described classically with predefined parameters.

Once a chemical model is chosen, the next step is to identify a level of theory that is suitable to study radical species (see also, **Radical Stability—Thermochemical Aspects**). For example, in our previous work on the reactions catalyzed by coenzyme B₁₂-dependent enzymes, high-level conventional *ab initio* and density functional theory (DFT) procedures were used.³ Relative energies were often obtained with high-level composite methods such as G3(MP2)-RAD⁶ or CBS-RAD,⁷ that have been found to perform well when assessed against reliable thermochemical data for reactions related to those being investigated.⁸ In addition, the more economical B3-LYP^{9–11} DFT method with a large basis set was often found to be comparable in performance for these systems to that of more expensive procedures, thus providing confidence in its use when the computational cost of higher level *ab initio* methods becomes prohibitive. QM/MM schemes typically use a DFT procedure for the QM region in combination with a standard force field (e.g., AMBER¹²).

The aim of this review is to provide an overview of how theoretical modeling has been applied to the understanding of reactions catalyzed by enzymes that rely on radicals (the so-called radical enzymes,^{13–15} see also **Radical Enzymes**). We note that the enzyme systems reviewed herein are not intended to represent an exhaustive overview of this field. Instead, an attempt is made to show the reader examples of the kinds of radical-related biological problems that can be addressed with theory. Thus, the rich and extensive theoretical work on cytochrome P450 is excluded,¹⁶ as are the reactions catalyzed by methane monooxygenase.^{17,18} In fact, we do not include any situations in which the formal radical center is located on a metal that participates directly in the substrate catalysis. A proper description of such metalloenzymes often requires a specialized theoretical treatment, such as broken-symmetry DFT for multimetal systems,^{19,20} and is beyond the scope of this article. The reader is directed elsewhere for excellent reviews on

these topics.^{21–25} In this article, we discuss the reactions catalyzed by coenzyme B₁₂-dependent enzymes, the glycol radical enzymes pyruvate formate lyase (PFL) and benzylsuccinate synthase (BSS), class III ribonucleotide reductase (RNR), and methyl-coenzyme M reductase (MCR). Collectively, these examples represent a broad range of radical enzymes for which theory has played an important role in contributing to understand their mechanisms of action.

2 COENZYME B₁₂-DEPENDENT ENZYMES

Enzymes that rely on coenzyme B₁₂ (5'-deoxyadenosylcobalamin, AdoCbl) are involved in physiological pathways that are vital to life, including energy generation and DNA synthesis and regulation.²⁶ The reactions made possible by these enzymes share a common origin in that radical intermediates are used to interchange a hydrogen atom (H) and functional group (X) on adjacent carbon atoms of the substrate (1)²⁷:

One of the defining features of AdoCbl-dependent enzymes is the identity of X which, depending on the enzyme, is either a small carbon-skeleton fragment (class I) or a small heteroatom-containing group such as OH or NH₂ (classes II and III). The accepted mechanism for these reactions is shown in Scheme 1,²⁶ which begins with the homolytic cleavage of the Co–C bond of AdoCbl to generate the 5'-deoxyadenosyl radical (Ado•) plus cob(II)alamin. Ado• serves to abstract an H atom from the substrate (**1**) to form 5'-deoxyadenosine (Ado–H) plus a substrate-derived radical **2** (step A). Rearrangement of **2** then gives the product-related radical **3** (step B), which is followed by a second H-atom transfer between Ado–H and **3** to give the product **4** and to regenerate Ado• (step C). In some cases, elimination of H₂O or NH₃ from **4** occurs to produce an aldehyde (**5**, step D). Understanding the details of each step of Scheme 1 has attracted considerable interest over the years, both because of the biological importance as well as the simple yet elegant chemistry that is involved. In the next few sections, we highlight the insights that have been gained through

Scheme 1 General mechanism for the rearrangements catalyzed by coenzyme B₁₂-dependent enzymes.³ [Reprinted with permission from Ref. 3. Copyright 2010 American Chemical Society.]

computational modeling for the reactions catalyzed by a variety of AdoCbl-dependent enzymes.

2.1 Co–C Homolysis

One of the most contentious issues concerning the reactions catalyzed by coenzyme B₁₂-dependent enzymes is how the Co–C bond of AdoCbl is cleaved and how this step is coupled to the ensuing H-atom abstraction step. Arguably, one of the most complex coenzymes in nature, AdoCbl possesses a six-coordinate central cobalt atom that is flanked by a corrin ring, 5,6-dimethylbenzimidazole (DMB) as the lower α -axial ligand and 5'-deoxyadenosyl (Ado) as the upper β -axial ligand. The C5' atom of Ado forms a σ -bond to the central cobalt atom—a very rare chemical bond in nature—whose length has been determined as 2.03 Å in a recent high-resolution X-ray structure (Figure 1).²⁸

The bond dissociation enthalpy (BDE) of the Co–C bond of AdoCbl in solution is $\sim 130 \text{ kJ mol}^{-1}$ and is associated with a thermal homolysis rate at 25 °C of just $10^{-9\pm 1} \text{ s}^{-1}$.²⁹ Remarkably, AdoCbl-dependent enzymes enhance the rate of Co–C cleavage by up to one trillion-fold, implying that the enzyme reduces the BDE relative to solution by roughly 60 kJ mol^{-1} . Clearly, this unprecedented chemistry is made possible by an extremely efficient and well-regulated mechanism. But how is this achieved? Responding to this question has been a challenge to researchers in the field for almost 40 years.³⁰

Figure 1 Isolated coenzyme B₁₂ (5'-deoxyadenosylcobalamin, AdoCbl) obtained from X-ray crystallography.²⁸

Several mechanisms have been considered to account for the dramatic rate acceleration of Co–C bond cleavage of AdoCbl in the enzyme environment.³⁰ Often, the interaction between the cofactor and the enzyme is cited to play a major role in AdoCbl activation. In the absence of coupled Co–C bond homolysis and H-atom abstraction from the substrate, the dissociation of the Co–C bond may be regarded as a Morse potential curve whose energy rises with increasing Co–C bond distance.³¹

In this scenario, there is no transition structure (TS) along the reaction pathway, and so facilitating the homolysis requires either destabilization of the reactant state or stabilization of the product state or some combination of the two.

Early structural and spectroscopic studies tended to favor a mechanism involving ground-state destabilization. In particular, the mutases belonging to class I²⁷ were thought to operate by this mechanism since these enzymes displace the lower α -axial DMB ligand of the cofactor for a mobile endogenous histidine residue from the enzyme. Furthermore, it is known that modifications to the lower α -axial ligand have the ability to influence the bond strength of the upper β -axial ligand.³² Another hypothesis put forward to account for Co–C bond activation in AdoCbl is the so-called mechanochemical triggering (or the *trans*-effect).³³ In this proposal, Co–C bond cleavage is accelerated via enzymatic compression of the Co–N_{ax} bond. Such compression is understood to elicit unfavorable steric interactions on the lower face of the corrin ring, which causes an increase in the upward fold angle of the ring.

Various spectroscopic studies with methylmalonyl-CoA mutase (MCM)—including resonance Raman,^{34,35} electronic absorption (Abs), and magnetic circular dichroism (MCD)³⁶—have suggested that ground-state destabilization is likely to contribute little to the rate acceleration of Co–C bond homolysis. Instead, product-state stabilization is suggested to be operative.³⁷ Again using MCD and Abs, and in conjunction with DFT calculations, significant deviations in metal-to-ligand charge transfer in the MCM-bound Co²⁺ Cbl species were observed, both in the presence and absence of a substrate.³⁷ The source of stabilization was identified to be the Co²⁺ 3d orbitals, and it was postulated that product-state stabilization is enhanced by proton uptake from the “catalytic triad.” Concurrent MCD and Abs studies with the related glutamate mutase (GM) revealed spectra similar to those of MCM,³⁸ indicating that the Co²⁺ 3d orbitals of AdoCbl may also be important in stabilizing the product state in this enzyme. Taken together, these studies imply that a common mechanism might be operational for Co–C bond activation for the class I mutase family of AdoCbl-dependent enzymes.

Combined QM/MM studies on MCM,³⁹ and GM⁴⁰ have also been performed to determine the Co–C bond-cleavage mechanism.⁴¹ In MCM, a

significant conformational change in the adenosyl portion of AdoCbl was found to precede the actual Co–C bond cleavage, which was interpreted to suggest that a two-step process for homolysis is operative.³⁹ The barrier for Co–C bond cleavage was determined to be ~ 40 kJ mol^{−1} and the reaction was found to be endothermic by ~ 10 kJ mol^{−1}. Interestingly, the large conformational change observed in the cofactor positioned the resulting 5'-deoxyadenosyl radical (Ado•) close to the substrate for subsequent hydrogen-atom abstraction.³⁹

In computational studies of GM, four components that contribute to lower the energy for Co–C bond homolysis were identified⁴⁰: (i) the enzyme keeps Ado• bound at a Co–C bond distance of 3.2–4.2 Å, which is equivalent to the so-called cage effect and corresponds to a decrease in the computed BDE of 20 kJ mol^{−1}; (ii) there is differential electrostatic stabilization of the Co(II) state by the surrounding protein, which amounts to a decrease in the BDE of the Co–C bond of 42 kJ mol^{−1}; (iii) there is van der Waals and electrostatic stabilization of the surrounding protein in the Co(II) state, which amounts to 11 kJ mol^{−1}; and (iv) the enzyme distorts AdoCbl, especially in the Co(III) state. This last contribution was shown to provide the dominant catalytic contribution to Co–C homolysis, amounting to 61 kJ mol^{−1}. It is notable that Brooks *et al.*³⁸ have questioned the validity of these computational studies because the geometric distortions predicted for the Co(III) state are not consistent with their spectroscopic data.

Buckel *et al.*⁴² have recently proposed a new role for the cob(II)alamin portion of AdoCbl in the class I mutase family of enzymes. They suggest that it acts to stabilize radical intermediates in the mutases and that by doing so, the energy of the TSs for H-atom abstraction and rearrangement are lowered. In this scenario, cob(II)alamin is described as a “conductor” rather than the traditional view of it as merely being a “spectator” in the reactions catalyzed by AdoCbl-dependent enzymes. This proposal is principally based on the fact that the reactions catalyzed by these enzymes involve the reversible conversion of an unactivated methyl group to a methylene radical and the nonexistence of alternative sources for 5'-deoxyadenosyl radicals in the mutase family of enzymes.

Two computational studies have investigated whether cob(II)alamin can act as a conductor in the reactions catalyzed by AdoCbl-dependent enzymes.^{43,44} DFT calculations of a small gas-phase model relevant to GM found that a concerted pathway involving Co–C5' cleavage and H-atom abstraction is $\sim 30 \text{ kJ mol}^{-1}$ lower in energy than one that is purely stepwise, implying that cob(II)alamin can indeed act to modulate the energy requirements of the reaction.⁴³ However, in another study, it was found that whether a concerted or stepwise pathway exists is largely determined by the initial configuration of the system.⁴⁴ Specifically, the orientation of the ribose moiety of AdoCbl relative to the corrin ring is the key factor; the OH groups of the ribose are found to interact favorably in one configuration, amounting to a stabilization of $\sim 30 \text{ kJ mol}^{-1}$ relative to the relevant separated species. The interaction of C19–H of the corrin ring and O3' of the ribose appears to provide a lowering of the energy requirement for the concerted pathway, but the question was raised as to whether such interactions are relevant in the enzyme system.⁴⁴

Empirical valence bond (EVB) calculations of MCM provided support for a concerted pathway for Co–C5' cleavage and H-atom abstraction.⁴⁵ In this case, it was necessary to couple these steps in order to reproduce the experimental reaction free energy of approximately zero. Electrostatic interactions between the OH groups of the ribose portion of AdoCbl and an adjacent glutamate residue (Glu370) were identified as being important. In contrast, strain effects between AdoCbl and the active site of the enzyme were not observed and thus were considered not to be an important contributor to the catalysis. It was argued that such effects were overestimated in previous energy minimization schemes (e.g., QM/MM) because conformational sampling was not considered.

In contrast to these EVB results, a stepwise pathway for Co–C5' cleavage and H-atom abstraction in the MCM-catalyzed reaction has been advocated on the basis of QM/MM ONIOM(DFT/MM) calculations.⁴⁶ Models of increasing size were used to identify important contributors to catalysis. As before, the interaction of Glu370 with the OH groups of AdoCbl was identified as being important as well as the interaction of Gln330 to O1' of the ribose. Three contributors were found to affect Co–C bond cleavage: (i) the cage effect

contributes $\sim 20 \text{ kJ mol}^{-1}$; (ii) geometric distortions of AdoCbl in the enzyme, especially of the Ado moiety itself, amounts to $\sim 30 \text{ kJ mol}^{-1}$; and (iii) the protein MM effect due to electrostatic and van der Waals interactions of nearby residues with the Ado moiety contributes $\sim 40 \text{ kJ mol}^{-1}$. A concerted TS for the Co–C5' cleavage and H-atom abstraction could not be located. Indeed, relaxed scans along the Co–C5' coordinate with fixed C5'–H and substrate:C–H distances (where substrate:C refers to the methyl carbon of the substrate) showed the energy to rise sharply as the Co–C5' distance is decreased.

Most recently, we have performed an investigation of MCM that combines the effects of conformational sampling, as presented in the EVB study, with the first-principles nature of the QM/MM approach.⁴⁷ Our calculations provide strong evidence that the Co–C5' cleavage and H-atom abstraction occur in a stepwise manner and that the Ado' intermediate indeed corresponds to a minimum on the free energy surface. We find that the two ribose hydroxyl groups play a dual role in the catalytic process, as they facilitate the Co–C5' cleavage and assist the diffusion of the radical toward the substrate. Part of these effects can be attributed to the C19...O3' interaction, which is found to be relevant in the enzymatic environment. Its magnitude therein, however, appears to be somewhat less than that in the gas-phase treatments.⁴⁴ The overall mechanism is consistent with Rétey's idea of negative catalysis,⁴⁸ where the role of the B₁₂-dependent enzymes is not simply to lower energy barriers but also to manipulate highly reactive intermediates.

2.2 Class I Mutases

The class I mutases comprise a group of AdoCbl-dependent isomerases that mediate the interchange of a hydrogen atom and carbon-skeleton fragment on adjacent carbons. Members of this class include 2-methyleneglutarate mutase (MGM), glutamate mutase (GM), isobutyryl-CoA mutase, and methylmalonyl-CoA mutase (MCM). All these enzymes are found within the bacterial kingdom, but only the last one is also found in mammals. A longstanding problem for these enzymes has been to understand the mechanism(s) of the carbon-skeleton rearrangement (step B, Scheme 1), as several possible radical rearrangement pathways

can be conceived. We have explored a number of these possibilities using high-level *ab initio* procedures, as outlined below.

2.2.1 2-Methyleneglutarate Mutase

MGM catalyzes the reversible conversion of 2-methyleneglutarate to (*R*)-3-methylitaconate in bacterial fermentation(2)²⁷:

Considering the general mechanism of AdoCbl-dependent reactions, one can envision several ways in which this rearrangement might proceed via radical intermediates. In Scheme 2, we highlight four possible radical-based pathways that lead to the migration of a group X between adjacent carbon centers. One pathway (E), which is termed *fragmentation–recombination* (F/R), involves homolytic cleavage of the bond from carbon to X to yield two distinct species that can recombine at the adjacent carbon to produce the rearranged product-related radical. Pathway F represents a concerted rearrangement that does not involve complete fragmentation of the substrate. Instead, a bridged cyclopropyl-type TS connects

the substrate-derived and product-related radicals. In another pathway (G), the cyclopropyl-type species corresponds to a stable intermediate. This pathway requires the presence of appropriate unsaturation in the migrating group X, as found, for example, in 2-methyleneglutarate (2), to facilitate rearrangement. This so-called addition–elimination (A/E) pathway can then be described as the intramolecular addition of the unpaired electron to the π -system of X to form the cyclopropyl-type species, which can then ring-open via homolytic cleavage of the adjacent bond. Finally, pathway H involves protonation of the migrating moiety to facilitate a concerted rearrangement mechanism, since early theoretical investigations predicted that such a scenario lowers the energy requirements for rearrangement.^{49,50}

Using the but-3-enyl radical as a model for the substrate in the MGM-catalyzed reaction (Scheme 2, X = CH=CH₂, and (2)), pathways E, G, and H were investigated.⁵¹ Pathway E possesses a very large barrier of almost 150 kJ mol^{−1} for C–X bond cleavage, suggesting that this pathway is unlikely to be operational in the MGM-catalyzed reaction. Much lower barriers of ~40 kJ mol^{−1} were found for the ring-closing and ring-opening steps in the A/E mechanism (pathway G). Even more striking is the prediction that full protonation of the terminal methylene group in the but-3-enyl radical (pathway H) reduces the barrier for rearrangement to only ~10 kJ mol^{−1}.

Scheme 2 Possible 1,2-migration pathways involving radical intermediates.³ [Reprinted with permission from Ref. 3. Copyright 2010 American Chemical Society.]

Similar observations resulted from the use of an improved substrate model (i.e., the substrate-derived radical of 2-methyleneglutaric acid).⁵¹ In these cases, the reaction profiles were modified slightly due to intramolecular interactions as well as preferential stabilization of the radical center by the adjacent CO₂H group. Nevertheless, the qualitative finding that the F/R pathway lies considerably higher in energy than the A/E pathway is maintained. Moreover, the reduction in the rearrangement barrier accompanying protonation of the migrating group is again observed.

In terms of addressing the question of the preferred mechanism for rearrangement, the theoretical analysis identifies the intramolecular A/E pathway as being of low energy, especially when combined with protonation of the migrating group.⁵¹ On the other hand, on the basis of isotopic labeling studies and conformational arguments, it has been argued that an F/R pathway is the most consistent with the experimental results.⁵² Furthermore, kinetic modeling studies predict that an A/E mechanism would be too slow to account for the observed rate constant and, on the basis of these results, a modified version of the F/R pathway involving *heterolytic* cleavage of the ionized substrate-derived radical has been proposed.⁵³ Clearly, further research is required to reconcile these seemingly conflicting conclusions. The availability of a crystal structure for MGM, which would enable more detailed molecular modeling, would undoubtedly prove useful in this regard.

2.2.2 Methylmalonyl-CoA Mutase

In humans, MCM is involved in the catabolism of odd-chain fatty acids, branched-chain amino acids, and cholesterol via the reversible rearrangement of methylmalonyl-CoA to succinyl-CoA (3)²⁷:

Problems associated with this transformation can lead to methylmalonic acidemia, a potentially fatal disease characterized by excessive levels of methylmalonyl-CoA.⁵⁴

Like the MGM-catalyzed reaction, the presence of unsaturation in the migrating thioformyl-CoA moiety allows the possibility of both A/E and F/R rearrangement pathways. Similarly, the barrier for the F/R pathway is calculated to be quite high (93.2 kJ mol⁻¹) when 3-propanal radical is used as a model for the substrate-derived radical of methylmalonyl-CoA.^{55,56} A considerable reduction in the rearrangement barrier is observed for the intramolecular A/E pathway (to 46.9 kJ mol⁻¹). Even more striking is the finding that the barrier is reduced to just 10.0 kJ mol⁻¹ when the carbonyl oxygen is fully protonated. However, because it is very unlikely that the carbonyl oxygen would be fully protonated in the enzyme environment, the possibility of *partial* protonation by the enzyme was explored using a series of small gas-phase molecules as potential proton donors (Figure 2).^{55,56}
